The Incapacity to Receive Kindness

What is it that makes it so hard for people to take? What lies behind this incapacity to receive kindness? The following are some of the motives concerned: (1) That that particular form of kindness is not desired at all. (2) The receiving of kindness may make the recipient feel inferior. (3) The recipients must not allow themselves to receive anything at all. (4) It prevents the recipient from the joy of feeling themselves to be hurt, badly used, or martyrs.

I

To take the first of these motives—that the particular form of kindness is not desired; most people know that rather interfering kindness offered to satisfy some desire of the giver. It is illustrated very well in the giving of Christmas presents. "I must give Dolly something. What will do? Oh, I know! that orange tablecloth that I bought at that Sale of Work last week." There is no thought that perhaps Dolly may not use tablecloths, or even if she does the orange cloth may not go with the cerise flowers on the breakfast service. Again, it is of no use offering a person something that they have no room for, which is the same as having no wish for. It is no use assuming that they would like it because one would like it oneself. The offering then falls where there is no space for it, where no response is possible.

II

The second motive behind the inability to receive was that it made the recipient feel inferior. Why? It is not the fault of the kindness alone, or of the recipient alone, which makes the latter feel inferior, but of the relationship between the two. The kindness which increases the inferiority feeling of a person is the kindness which includes pity, and extremely few people can endure to be pitied. Although it is said that pity is akin to love, it may also be perilously akin to contempt. For a person to be conscious of being pitied is for them to be conscious of how very little they have in comparison with the person pitying. They feel powerless, unimportant, and dependent, and the feeling gradually arises—"How dare they make me out to be nobody! I don't want their pity, blast them!"

It is a very common thing, this feeling of inferiority, when there does not seem to be any power to get things from life. Superiority, power, and well-being go so very much hand-in-hand with the quantity of material possessions, including brains, and physical charm and beauty among those material possessions. It must always be so as long as to feel good, to have a feeling of well-being, means to possess much; as long as quantity is confused with quality. There is another feeling of the recipient of kindness, which says, "I don't want them to do it out of kindness, but because they want to do it." This gives a definition of kindness—the doing something for another person, and the recipient says, "I don't want them to do anything for me. What I really want is for them to love me." This was very aptly illustrated by the patient who said, "I am only a patient whom you are being decent to."

This type of inferiority is very largely mitigated by the giving of something back. The same patient was invited by the analyst to share a taxi, as they were both going for a short distance in the same direction. The patient said, "Oh, no, it wouldn't be fair," the idea being that it would only be fair if she paid part of the fare. She could not allow herself to have anything unless she balanced it by an equal giving. The second patient who dreamt about the brooch, it was seen also dreamt that she was trying to find *something to give.* Both these patients felt undervalued; the one with the taxi because she herself could not afford the fare of a taxi, and she did not feel that she was giving her analyst anything by accompanying her. She never felt that she was capable of giving anyone any pleasure by her presence. The patient of the brooch-dream felt undervalued because it accentuated how little value she had when measured by material possessions.

There is a very strong instinctive tendency that something must always be given "for value received." It would seem quite true, and to be a question of balance and relationship and to work something like this. Before a baby is born it has warmth, safety, comfort, and food whenever it wants it, or even before it knows it wants it. There is no want and no desire; the relationship inside the mother can be called a balanced relationship, or, better still, a neutralised relationship.

In a book on landscape painting by a well-known artist now dead, a good deal of space is given to the question of arrangement in pictures, and a sketch is shown in which the arrangement on one side is balanced by by the arrangement on the other.

Thus there are two hills, one on each side of the picture, each side matches, the sketch giving the impression of being quite dead. The same effect can be obtained by the arrangement of furniture in a room. For instance, a table can stand exactly in the middle of the room with half-a-dozen books round it at equal intervals apart; or the arrangement of a mantelpiece may be as follows: the actual mantelpiece held two objects, a picture, or rather two pictures in a double frame hinged together, and a clock. Above was a mirror very little larger than the breadth of the double picture when opened out. Beneath the mantelpiece was, of course, the fireplace. The clock, a very small one, stood at one end of the mantelpiece, but the picture was exactly under the mirror, right in the centre. The arrangement very considerably took away from the value of the picture.

A second picture followed the neutralised one of the landscape book, a picture in which nothing matched and very little was on the same level. A second arrangement of the mantelpiece came about, in which all that was moved was the picture, and that was moved to the other side of the mirror.

The first picture was dead, and the first arrangement of the mantelpiece was dead; they left the impression of there being no further use for them. The second picture and the second arrangement of the mantelpiece were alive, because they gave the impression of an unbalanced scale, leaving the observer to supply the other side of the balance and so form a relationship.

With the baby before birth there is no relationship because there is no unbalance. Likewise with the patient and analyst, at the beginning, and for the first part of the treatment, there is no relationship because there is no unbalance on the part of the patient. The receiving of value for which nothing is given in return creates an unbalance, which the patient cannot tolerate. It is the capacity to tolerate the unbalance which brings relationship with all that follows in its train into the realm of possible things.

III

Following on what has been said above is the third of the motives behind the inability to receive kindness, the motive that will not allow the recipients to receive anything at all. They are not *open* to kindness. It is not possible to put anything where there is no space for it; the patient has balanced himself and there is no room within the balance for anything else. Both sides match and are equal; there is no swing and no movement; nothing can be taken in. The patient is in the same position as the baby inside the womb; the balance has been formed because the patient could not possibly tolerate the unbalance; thus there is no room for kindness, or for anything to be received; there is nowhere to put it without turning something else out. "It is more blessed to give than to receive" can be taken in more ways than one.

IV

The fourth motive—that kindness prevents the recipient from enjoying being hurt, or feeling badly used, or posing as a martyr, is really all much of a piece with the third one that has just been discussed. It would seem to work this way: The child in the womb has everything it wants before it wants it, and there can be no unbalance. After birth, this state of things no longer exists and the baby has to wait for its food, and to become accustomed to not having what it wants even when it wants it. In other words, it must endure unbalance and a small space of *not having* is entering into its life. It varies in size, and may be very, very small, but there it is, and the question of unbalancedness is the question of keeping that space free and open, so that the balance can move and take in anything that comes along and does not remain a fixed balance. If both sides of the balance are cluttered up, it stays put, and nothing can be taken in without first turning something out.

Now the possible things that can be put into that small space to make the balance are numerous, and martyrdom and enjoyment of being hurt are of the number. Kindness, something given, threatens to turn something already possessed out of the balance. One of those things has been said to be martyrdom. It is a curious but very real pleasure that certain people get out of this feeling, and anything given to them in a direct fashion is unwelcome, because then the feeling of martyrdom and ill-usage is very difficult to maintain. The enjoyment of ill-usage can go to great lengths, even to the pleasure in seeing someone else made a favourite of, because it increases the feeling of ill-usage. It seems almost past belief that anyone should enjoy these feelings: so why do they?

The original feeling is: "I want to be everyone's favourite, and to be loved and valued very highly, but I find I'm not." That is an unbearable situation, and there are several things which the patient can do about it. One is: "I can't have the pleasure of being the best treated so I will have the pleasure of being the worst treated." There is distinction in being the worst, the patient is not of the common herd. In this case, kindness threatens the loss of the distinction which is so much valued. There is another very unpleasant habit which illustrates this point. It is the habit that some people have of saying: "Of course, I don't matter." The remark may be a perfectly genuine one, and the person may not matter in that particular circumstance, which fact he may be understanding and accepting, but as a rule it is the sign of the false martyr. Tremendous satisfaction is obtained by not having value, because if dissatisfied with the value he did receive the patient would find it too painful to bear, so it becomes a pleasure not to have it or to be undervalued.

A patient, married, aged 34, came in one day grumbling furiously because the waiting-room had a few odd things about and was not as tidy as usual. It was just before Christmas, and the patient said "Of course the house was kept for the doctors, and the patients only came second: they did not matter." The doctor said: "Well, it is just Christmas time: you must excuse it this once. I don't expect it will be like that again."

The fury of the patient when she came in was as nothing to the fury she exhibited after this remark. She had been thoroughly enjoying her own martyrdom, and the doctor, quite unthinkingly, pricked the bubble. She did not get over it for the whole hour, and nothing that the doctor could say was of the slightest use. It often occurs that anger and hatred are directed against the givers of kindness. Resentment is felt by people against one who makes them feel inferior, or who takes away from them, however unwittingly, their chosen joy.

The Giver and his Motives

A great deal has been said about the recipient of kindness. What, now, of the giver and his motives? Why does he want to give? (1) To be important and to have power. (2) To create an emotional situation, and to gain love. (3) To relieve a painful situation. (4) As a compensation for feelings of unkindness. (5) To maintain a balance.

I

To be important and to have power is the driving force or motive power behind very many activities, and one of the methods of obtaining these things, or rather of feeling oneself to have obtained them, is to be in the position to bestow gifts, privileges, and kindnesses of various sorts. The tiny baby has everything given to it, and later may come to look upon the condition of receiving as one of inferiority.

What an enormous superiority is to be found attached to the position of the person who gives, who has many possessions, or much money to give away! How very inferior feels the person who is unable to give an adequate tip! And again, how marvellously superior it may feel to be in the position of Lady Bountiful! Even more superior is it to be able to pull strings! "I'll put a word in for him, Mrs. ——" or "I could have got you in if you had come to me about it" are quite frequent remarks from people in positions of importance, and how the ones that feel inferior long to be able to say it too!

A patient, aged 39, was in the habit of bringing her doctor flowers, but she always brought a very curious assortment, such as a few daffodils, two tulips, a bunch of violets and a piece of lilac. When asked why she brought such a varied bunch she did not quite know, but she thought that she wanted her doctor to feel that she had a very wide choice so that she could feel superior.

II

Gifts are often brought and kindnesses done in order to create an emotional situation. This is very well illustrated by patients. The gift must be brought in person, so that they may be thanked, and it feels as if there is a much closer relationship with their analyst than before. They go away from the interview feeling that their analyst is pleased with them, and thinks how nice they are, and it all feels very intense, which is what they want. They feel themselves to be loved and to be of value. Under the same heading in everyday life comes the embroidering of slippers for the curate, or the "pair of (offertory) bags worked for the vicar by a lady of the congregation." Another aspect of this comes out in a sort of vicarious kindness very well illustrated by that very delightful children's book, "The Wild Ruthvens." The book deals with a family of boys and girls, the eldest girl being very much attached to a curate of the neighbouring church. The amount of kindness expended on the boys' Sunday-school class compared with the very conspicuous lack of it shown at home, is amazing.

III

Kindness is often the result of a desire to relieve a painful situation. It is undoubtedly a horrible thing to see pain and suffering in another individual, and it becomes very intensely painful when seen in a loved person. Of course, the natural instinctive reaction is to say: "I can't bear this. I must do something about it at once; this situation must be altered quickly." An anxiety situation has arisen. It is all very well to make an effort to relieve the painful situation, but it is advisable to have some idea as to whether the desire to alter it is to relieve the pain of the suffering person, or to relieve one's own anxiety and consequently unbearable feelings. This latter type of kindness may be devastating, and it also very often results in the "weariness in well doing," because it is often not very far-seeing and the giver finds it very difficult to bear the fact that the situation is not really relieved, but owing to mistakes must lapse again and again into the same old situation. The giver in these cases is apt to get very exasperated, and even annoyed, and is inclined to feel that he can never get rid of his protégés, and that they are always asking him for things.

IV

To be kind as a compensation for feelings of unkindness is very common indeed. Children are usually brought up that to show animosity is wicked, and that they will not be loved if they do show it, or at any rate they will be very strongly disapproved of. The result is that they come to disapprove of themselves for having feelings of animosity, and the feeling is repressed or ignored and is sometimes balanced by an excessive kindness.

There was a girl, aged 14, who had a stepmother. The latter was not physically cruel, but was very jealous of and the position the child occupied in relation to her father, she made the child's life an absolute misery. At Christmas, and on her birthday, however, the stepmother produced marvellous presents, thereby completely bewildering the child, who felt she was being unjust and horrible in her estimation of her stepmother.

Another frequent example of compensatory kindness is the daughter's care for the widowed mother. The following is an interesting case in which there was a brother and sister, and a mother widowed at a very early age.

The boy, who was very devoted to his mother, grew up very fair, with beautiful wavy hair, and a rather womanish expression. He was very popular socially, very artistic, and had very second-class brains. Moreover, as has been said, he was very fond of his mother. He is now about 40, or a little more, and of all the years since he left school at 18, he has been about 10 years only in England.

The girl grew up, very intellectual, not very feminine, and obviously cut out for a university career. She has stayed at home to look after her mother, though her feeling is almost one of hatred and her jealousy of her brother is unmistakable. Her cry has always been: "I can't leave mother." She sees now, at this very late stage of proceedings, that at one time she could have left, but it is now too late as her mother is actually too old and infirm to be alone.

This type of kindness based on the motive of unkindness is the type that kills. Very little thought is given to the recipient and to the things they would like done. It can even be used as a weapon of attack. It is very easy to kill by kindness where the original motive is to kill.

V

Giving can maintain a balance. Something has been said about the inability to put anything where there is no place for it unless something is turned out, and this question brings in the relationship of kindness to guilt. Guilt can be described as the feeling maintained by the balance being made up of something that does not really belong there. If there is anything in the wrong place, discomfort results; but how has it got there? It is quite obvious that it has been put there, and it is more than probable that it is the possessor himself who has put it there; taken it out, so to speak, of its right place and time and put it in the balance. If that is so, then a space which in its turn should not be there has been left from whence the original something was taken. As a vacuum is intolerable, something must be turned out to put in the place left vacant. The person concerned manages quite well as long as he can delude himself that the vacuum is not there, as long as it is not brought to his notice by anything outside. As soon as he realises its existence, then he feels uncomfortable and must do something about it. He feels he must not, or ought not to receive anything and that if he does he must either pay it back at once, or deprive himself of something else. He may even react by anger punishing the person who is kind to him, because he feels he really should punish himself for taking the kindness or for the original theft.

The instinctive life will always fill up gaps, emptiness is unbearable—"Nature abhors a vacuum," so that any feeling of emotional emptiness is dealt with by removing something from the surrounding medium and putting it in the empty space. The remover then feels balanced and complete, though it may be a stolen balance, and a stolen completeness. And of course, there is no room for anything to come in, no room to expand and grow; and moreover there is that empty space outside; the person whose character one would like to take away must be praised to the skies, and the person whose possessions one would like to remove, and emotionally does remove, must be given things. It is very interesting to notice what excellent testimonials may be given where the employed person is unconsciously disliked.

In conclusion it may not be out of place to make a few remarks about cruelty. Cruelty is kindness reversed, and as much cruelty is perpetrated in the name of kindness, and by its technique, as by the recognised methods of cruelty. It consists in giving people what they do not want, and in withholding from them something that they do want. How much of that is done in the name of kindness, and more than ever in the name of Charity? True charity is composed of the two sorts of kindness: that which gives and that also which lets be; and that which lets be is much the rarer of the two. Why? Because in the worship of action and in the anxiety to relieve a painful situation, it is not usually thought that there is as much power in inaction as there is in action: that the former can be as much a manifestation of love as that which tries to do something about it. There is no truer description of kindness, charity, or love, which are all one, than the old familiar text in the Bible:

> Charity suffereth long and is kind; charity envieth not; vaunteth not itself, is not puffed up, doth not behave itself unseemly, seeketh not her own, is not easily provoked, thinketh no evil; rejoiceth not in iniquity, but rejoiceth in the truth; beareth all things, believeth all things, hopeth all things, endureth all things. Charity never faileth; . . .

It would be difficult to find a more perfect description of the acceptance of *not having* and *not doing*, which is the essence of that charity, motivated by love and including kindness. Action itself is the offspring of a love relationship, the child, not one of the parents, and before that relationship takes place both parents *have not*.

Finally, kindness does not maintain a balance: it is an ever-widening circle, but neither the kindness given nor the kindness received attains its full fruition until it circulates, and ultimately comes back to the giver to be sublimed and circulated again on a higher level of the spiral.

"Cast thy bread upon the waters and thou shalt find it after many days . . ."

TRAVEL AND EXPLORATION

To launch a new journal at the public is nowadays an anxious venture, but there can be no doubt of the welcome that awaits the *Geographical Magazine*. Its scope is much the same as that of the *National Geographic Magazine* of America, which has long and deservedly enjoyed a large circulation here as elsewhere. It consists of signed accounts of travel or observations both at home and abroad, and it is illustrated so freely and well that it will appeal to children almost as much as their elders. The first issue, dated May, 1935, contains articles on Abyssinia, the Lake District as a national park, Rajputana, the Arctic air route, the desert highway of North Syria, India's north-east frontier, and the changing face of Amsterdam, while Dr. Brian Maegraith describes, with fascinating photographs, the life of "our stone-age contemporaries" the aborigines of Central Australia. Judging by beginnings, the editor, Mr. Michael Huxley, will be successful in his aim—to make the dry bones of geography live. In so doing he hopes to provide incidentally an understanding of world problems which no other periodical can give.

The *Geographical Magazine* is published by Messrs. Chatto and Windus from 40, Chandos-street, London, W.C. 2, at 1*s*. The annual subscription (post free) is 15*s*., and half of any profits earned will be assigned to a fund for the advancement of exploration and research, and the promotion of geographical knowledge. The trustees administering this fund are to meet under the chairmanship of the president of the Royal Geographical Society.

Appointments

BATCHELOR, G. F. GRANT, F.R.C.S. Eng., has been appointed Honorary Surgeon to the West London Hospital.

DOUGLAS, J. B., M.B. St. And., Chief Assistant in the X Ray Diagnostic Department of St. Bartholomew's Hospital, London.

DUTHIE, R. J., M.D. Aberd., Hon. Assistant Physician to the Aberdeen Royal Infirmary.

JACKSON, HARVEY, F.R.C.S. Eng., Honorary Assistant Surgeon to the West London Hospital.

KEERS, R. Y., M.D. Edin., Second Assistant Medical Officer to the King Edward VII. Sanatorium, Midhurst.

MOORE, A. M. A., F.R.C.S. Eng., Hon. Assistant Surgeon to the Poplar Hospital for Accidents.

MOWAT, G. GORDON, M.B. Camb., F.R.C.S. Edin., Honorary Aural Surgeon to the Royal Infirmary, Bolton.

NORRIE, F. H. B., M.B. Ch. M. Aberd., F.R.C.S. Edin., Hon. Junior Surgeon to the Ear, Nose, and Throat Department of the Aberdeen Royal Infirmary.

NORRIE, F. H. B., M.D., Ch.M. Aberd., F.R.C.S. Edin., Honorary Assistant Surgeon for Diseases of the Ear, Nose, and Throat at the Royal Aberdeen Hospital fo

POCOCK, J. A., M.B. Camb., F.R.C.S. Officer to the St. John's Hospital, Lewisham.

WHALEY, J. B., M.D., D.L.O., Resident Aural Registrar to the Hospital for Sick Children, Great Ormond-street.

WILLIAMS, E. ROHAN, M.D., M.R.C.P. Lond., D.M.R.E., Assistant Medical Officer in Charge of the X Ray Department, St. Mary's Hospital, London.

WOODHAM, C. W. B., M.R.C.S. Eng., Research Officer in the Deep X Ray Therapy Department of St. Bartholomew's Hospital, London.

London County Council Hospital Staff.—The following appointments, promotions, and transfers are announced. A.M.O. (I.) and (II.) = Assistant Medical Officer, Grades I. and II.

BAIN, W. I., B.Ch. Camb., A.M.O. (I.), Queen Mary's Hospital for Children.

SCOTT, M. H., M.B. Lond., A.M.O. (I.), Queen Mary's Hospital for Children.

HUGHES, J., B.Ch., A.M.O. (I.), Downs Hospital for Children.

COLBECK, S. C., M.B. N.Z., A.M.O. (I.), Grove Park.

COOPER, P. T., M.B. Camb., A.M.O. (I.), St. Pancras.

ROBSON, J. S., M.B. Belf., A.M.O. (II.), Constance-road Institution.

COOKE, S. C. S., M.R.C.S. Eng., A.M.O. (II.), Dulwich.

STEVENSON, A. C., M.B. Glasg., A.M.O. (II.), Highgate.

BUGGLE, G. A., L.R.C.P. Dub., A.M.O. (II.), Holborn and Finsbury Institution.

SAYCE, A. M., M.B. Wales, A.M.O. (II.), Paddington.

DISNEY, M. E., M.B. Lond., A.M.O. (II.), Queen Mary's, Sidcup.

DRUKER, J., M.B., Ch.B. Manch., A.M.O. (II.), St. Benedict's.

BRUCE, R. D., M.B. Aber kney.

KETTLEWELL, H. B. D. Physician, Hackney.

CAFFELL, T. E., M.B. N.Z., House Physician, St. Alphege's.

BARKER, G. A., M.R.C.S. Eng., House Physician, St. Giles.

CAREY, W. A., L.R.C.P. Lond., House Surgeon, St. Giles.

OVENS, G. H. C., M.R.C.S. Eng., House Physician, St. James.

LENANTON, G. A. R., M.R.C.S. Eng., Clinical Assistant, St. Mary Abbots.

JOHNSON, W. A., M.R.C.S. Eng., House Surgeon, St. James.

HOPKIN, D. A. B., M.R.C.S. Eng., House Physician, St. James.

REID, J. OWEN, M.D. Edin., Senior A.M.O. (I.), St. George-in-the-East.

SIMPSON, W., M.D. Glasg., A.M.O. (II.), St. Alphege's.

MURPHY, F. D., M.B. Irel., Senior A.M.O. (II.), Paddington.

GRAHAM, W. H., M.B. Glasg., F.R.C.S. Eng., Senior A.M.O. (II.), St. Mary's Islington.

CUSSEN, K. R., M.B. Melb., A.M.O. (I.), St. Luke's Hospital, Lowestoft.

JONES, A. N., M.B. Liverp., F.R.C.S. Eng., A.M.O. (I.), Bethnal Green.

GOLDRING, H. J., M.B. Belf., A.M.O. (I.), Lambeth.

SMITH, D. B., M.B. Toronto, A.M.O. (I.), St. Stephen's.

DOUGLAS, A. M., M.B. N.Z., A.M.O. (I.), St. Stephen's.

CUNNINGHAM, A. A., M.B. Dub., A.M.O. (I.), South-Eastern.

Certifying Surgeons under the Factory and Workshop Acts: Dr. M. ZIMMERMAN (Marlow, Buckinghamshire); Dr. R. A. K. WIENER (High Wycombe, Buckinghamshire).

SHEFFIELD ROYAL INFIRMARY.—This institution continues to treat patients to the limits of its capacity, and the total expenditure of £68,031 last year increased by over £3000 as compared with 1933. The income of the hospital shows an increase of well over £9000.

BRISTOL ROYAL INFIRMARY.—There was an increase in both in-patients and out-patients at this hospital during last year. There was also an increase in ordinary income, but the ordinary expenditure exceeded income by over £10,000. Under the heading of extraordinary expenditure the largest item was £2952 for bank charges. The average cost per occupied bed was £2 19*s*. 8¾*d*., as compared with £2 18*s*. 4*d*. last year and £2 19*s*. 9*d*. in the previous year.

ADDRESSES AND ORIGINAL ARTICLES

URETERO-VAGINAL FISTULA*

By A. E. Webb-Johnson, C.B.E., D.S.O., F.R.C.S. Eng.
SURGEON TO THE MIDDLESEX HOSPITAL

It would be difficult to exaggerate the terrible discomfort which a woman must suffer if she has a constant leakage from the vagina as the result of a fistulous communication with the urinary tract. The external genital anatomy of women provides no such convenient arrangement as that with which men are blessed, and the instrument maker has failed to produce an apparatus which will ensure a woman's comfort when she is suffering from urinary incontinence. It follows that she is generally dependent on primitive arrangements in order to absorb the leaking urine and save her clothes and the furniture of herself and her friends from damage. In addition to the discomfort which necessarily results—and this must amount to mental agony in a fastidious woman—the constant presence of a pad soaked in urine, which is often infected, sometimes leads to most distressing soreness of the genitals and thighs.

The surgeon is naturally distressed when he sees a patient in such a miserable predicament, but his distress is magnified a hundredfold when the state of misery is the result of an operation which has been embarked upon with confidence and hope.

The justification for confining my remarks to uretero-vaginal fistula lies in the fact that during the last 23 years I have had to deal with 23 of these cases, and have arrived at certain conclusions as to the best line of procedure in preventing and treating the condition. As I have stated, this serious condition is generally the direct result of surgical intervention. All my cases except one have been the result of a pelvic operation. In the odd one, which was the first I had to deal with, the fistula developed after a difficult parturition, protracted labour, and instrumental delivery.

Injury to the Ureter : its Prevention and Repair

Before considering the question of treatment it will be well to devote a little time to the discussion of the prevention of injury to the ureters and the steps to be taken at the time if the surgeon realises that damage has been done. The uterus, bladder, and lower ends of the ureters are in such close relationship, and the normal anatomical arrangement may be so distorted when the uterus is the site of a tumour, that it is not surprising that the ureter is injured sometimes. Hysterectomy is so frequently performed that one may say that the ureters are in danger almost daily in the hospitals of a large city. Accidental damage still occurs too frequently, and it should be the guiding principle of the gynæcologist that it ought never to occur. In cases of fibroid tumour of the uterus the accident may happen without being noticed, but in Wertheim's operation for carcinoma, in the course of which the ureters are isolated, and maybe their blood-supply imperilled, the surgeon is well aware of the risk being run and has the ureters under his direct observation. In a case of carcinoma it might be impossible to avoid damaging a ureter, but in the operation of hysterectomy for fibroids it should be one of the rarest of all accidents instead of one which is fairly common.

Twenty-one years ago Sir John Bland-Sutton opened a discussion on this subject at the Medical Society of London and the discussion made it clear that the ureters were often injured during the performance of abdominal hysterectomy. The injury may not be noticed. Bland-Sutton expressed the opinion that it is possible and probable that a ureter has been tied in the course of hysterectomy and the patient has recovered without anyone having a suspicion that such an accident has happened. It is indeed true that there may be no serious effect if the urinary tract is free from infection, but it is well to bear in mind that it may be some time before interference with the lumen of the ureters is revealed. I have recently had in my wards a case of nephrectomy for pyonephrosis in a woman who had a pelvic operation three and a half years ago. I doubt not that the obstruction to the ureter which was 1 inch from the vesical orifice was the result of the pelvic operation. While nephrectomy is never undertaken without the most careful investigation of the urinary tract, surgeons must be doubly cautious if the patient has had a pelvic operation.

The ureter has been deliberately tied after accidental division without untoward signs. Numerous gynæcologists have confessed to tying the ureter and dropping it back. This has only to be mentioned to be condemned. Bland-Sutton emphasised the importance of dealing with a cut ureter at the time. As he wittily pointed out—"Kidney tissue is very precious. Many persons get on very well in the world with very little brains and some with none, but no one can live without a certain amount of kidney."

CHOICE OF PROCEDURE

There are various alternatives open to the surgeon when faced with this accident, and it is very desirable that a surgeon who is exposed to the risk of injuring the ureter should be prepared at once to repair the damage. He may attempt end-to-end union or he may graft the ureter into the bladder or into the colon. This last procedure would only be permissible if the injury were high up and a portion of the ureter had been removed. Fortunately, the injury when it occurs is nearly always quite near the vesical end of the ureter. End-to-end union is far from satisfactory. Only when the conditions are very favourable can a satisfactory union be made between the divided ends of the ureter. Moreover, should any narrowing occur it would not be so easily recognised or corrected as in the case of a graft into the bladder. I do not hesitate to say that the surgeon's duty is to implant the divided end of the ureter into the bladder. Great care is required in the performance of this operation, for if plenty of room is not left for the implanted ureter it may become sclerosed by chronic ureteritis which may narrow and even obliterate its lumen. The narrowing may be a gradual process and the obstruction to the ureter may lead to serious hydronephrosis or pyonephrosis after an interval of years.

This risk of narrowing can be avoided or minimised by careful attention to detail. In the first place a useful little manœuvre is to pass long fine forceps along the urethra and make them protrude on to a selected spot on the posterior wall of the bladder. A small incision is made on to the end of the forceps and the ureter drawn into the bladder by a thread which has been attached to it. The ureter can then be sutured to the bladder wall outside and a water-tight junction established. This method of grafting is not so certain of success as making the junction from inside the bladder. The surgeon need not hesitate to open the bladder during the course of an intraperitoneal operation.

---

* An address delivered to the Manchester Surgical Society on Dec. 4th, 1934.

If the bladder is opened and the ureter stitched in place from inside the viscus plenty of room can be left for the graft by leaving a gap below the suture line and passing a small drainage-tube through the posterior wall of the bladder into the retro-vesical tissues. The site of entry of the graft on the outside of the bladder can then be made extraperitoneal by suturing the pelvic peritoneum carefully over it.

If the bladder is not opened at the time and the implantation of the proximal end of the ureter is completed from outside the bladder the graft must generally be so closely sutured in position in order to make the junction absolutely water-tight that it is liable to become narrowed. If the implantation has been carried out in this way the graft should be kept under observation for some months and *the opening of the ureter examined at intervals through a cystoscope.* In this way any threatened contraction of the orifice, with the danger of damage to the kidney by obstruction and consequent increased risk of infection, can be recognised and dealt with either by dilating the orifice or, if necessary, by opening the bladder and improving the graft.

The surgeon may be labouring under the handicap that he is reluctant to call attention to the accident, but the interests of the patient demand that the graft should be kept under observation, and therefore the position must be faced and explained.

Treatment of Uretero-vaginal Fistula

I now pass to a discussion of the treatment of uretero-vaginal fistula. This may develop if the ureter has been cut and the injury has not been repaired, or if the blood-supply of the ureter has been so interfered with as to lead to sloughing of the lower end, or if the ureter or part of it has been included in a ligature or suture.

When it is noticed that there is a leakage of urine from the vagina the surgeon has first to ascertain from what part of the urinary tract the leakage is taking place.

First of all he must satisfy himself that the urine is not coming from the bladder. This is not so easy as one might expect. By careful observation and by the injection of coloured fluids into the bladder and ascertaining if any of the fluid finds its way into the vagina this point is however eventually cleared up. Being satisfied that the leakage is not from the bladder the surgeon must next ascertain from which ureter the urine is escaping. Fortunately he may easily get a very helpful clue to guide him in this investigation, for cystoscopy and the passage of a ureteral catheter may soon reveal the side on which the injury has been inflicted. The injured ureter is always obstructed whether it be completely divided or not. There is always obstruction to the passage of a catheter on the side of the fistula if it has been present a few weeks. This clue generally leads quickly to a definite diagnosis in cases following hysterectomy for fibroids, but in cases following Wertheim's operation the position is complicated by the fact that both ureters have been so disturbed and are embedded in such dense scar tissue on the floor of the pelvis that it is often difficult to pass a catheter into either ureter.

Eventually however—perhaps only after several attempts and with the use of very rigid ureteral catheters or bougies, reinforced with metal—a passage is found up one ureter while the other is found to be impassable. The side on which the obstructed ureter is found indicates the side on which the fistula is present.

In spite of the difficulties we may have to contend with in order to be absolutely sure on which side the lesion is situated, we are indeed fortunate compared with our forbears. A reference to Sir Henry Morris's Hunterian lectures delivered at the Royal College of Surgeons a short 36 years ago makes one realise the great advantages under which we work to-day. At that time it was computed that in any hundred hysterectomies, vaginal and abdominal, one or both ureters were tied or cut across in at least three. And Spencer Wells in 1881 stated that out of 94 published abdominal hysterectomies one ureter had been divided in six, and both ureters in two other cases. For these injuries nephrectomy was performed and in many instances healthy kidneys were removed. It would be bad enough to be misled as to the injured side at the present day and to proceed to expose the wrong ureter, but how tragic it must have been in the days of which Morris spoke, when nephrectomy was the accepted remedy and there were not the same facilities for diagnosis that we possess to-day.

In speaking of the difficulties experienced by surgeons trying to identify the kidney which was in connexion with the fistula Morris reported the following case:—

> "A woman who had undergone vaginal hysterectomy by a distinguished gynæcologist recovered with an uretero-vaginal fistula. The patient was handed over to a distinguished general surgeon to be cured of this fistula. Efforts were made in a most careful manner to ascertain which ureter it was which had been wounded and become entangled in the vaginal cicatrix. These failing to afford definite information, the ureter of the suspected kidney was exposed through a lumbar incision and was temporarily ligatured. During this experiment, which was of course made under chloroform, no urine escaped by the vagina, but a certain amount was withdrawn by catheter from the bladder at the expiration of a given time. The inference was that the ureter temporarily ligatured was the one involved in the vaginal fistula; so the corresponding kidney was there and then excised. Imagine the surgeon's chagrin, and the patient's distress, the next day when it was discovered that, though she had lost a healthy kidney, the operation had not cured her of the fistula; for the wrong organ had been removed."

Having ascertained which side is affected what should be done next? In 3 out of my 23 cases I have had the good fortune to force a catheter up an obstructed ureter with removal of the obstruction, followed by closing of the fistula. This experience leads me to recommend that serious efforts should always first be made to dilate the obstructed ureter through the cystoscope if exploration gives the least sense of the ureteral catheter or bougie being engaged in a stricture. The surgeon may notice after prolonged efforts, perhaps with a ureteral bougie or catheter which has been made more rigid by metal being interwoven in its structure, that the instrument is not easily withdrawn, giving the same sensation as that experienced when a gum-elastic bougie has become firmly engaged in a urethral stricture but has not passed through it. Further efforts may result in the passing of the catheter and cure may be expected.

If disappointment attend these attempts then the bladder should be opened.

The best results are to be obtained by resecting the lower end of the ureter through the bladder up to the site of the fistula and suturing the ureter into the bladder at a point above the fistula. The great advantage of an approach through the bladder is that, when the implantation is made, ample room can be left for the grafted ureter and all danger of the development of a narrow orifice avoided. On opening the bladder the previous observations are confirmed by passing a catheter up the intact ureter. A catheter is then passed on the fistulous side up to the site of obstruction. An incision is then made round the lower edge of the ureteral orifice and continued up the bladder wall. The lower end of the ureter is identified and dissected up until the fistula is reached. The lower part of the ureter, including the fistula, is then cut off and the divided end of the ureter is loosely sutured into the base of the bladder. A small drainage-tube is passed through the bladder wall below the implanted ureter into the retro-vesical tissues and fixed in position by a catgut suture, and a catheter is left in the ureter. The rest of the wound in the base of the bladder is closed and the bladder is drained through the suprapubic wound. The small tube draining the retro-vesical space is brought through the suprapubic wound and the ureteral catheter through the urethra. The ureteral catheter is removed in two days' time. The small tube is removed as soon as it becomes loose, and the bladder tube at the same time.

Convalescence is usually uneventful and the result a perfect and permanent cure. The operation is one of some delicacy and difficulty and takes some time to perform. It is more tiring and exhausting for the surgeon than for the patient, for in spite of the time it takes to complete the operation it is not associated with any shock.

This is what I consider the ideal way of dealing with these cases and in my opinion it should always be attempted. Sometimes it cannot be accomplished. This is more likely in the cases resulting from Wertheim's operation. After Wertheim's operation an incision through the base of the bladder leads into dense fibrous scar tissue in which it is always difficult and sometimes impossible to identify the ureter. If the surgeon fails to dissect out the ureter he should not hesitate to open the peritoneal cavity. He can then trace the ureter down to the floor of the pelvis and draw the lower end into the bladder through an incision in its posterior wall placed as low down as possible. It is helpful to attach a thread to the lower end of the ureter to assist in pulling it through into the bladder. The peritoneum over the pelvic floor should then be carefully sutured and the peritoneal cavity closed. The surgeon can then proceed to deal with the implantation of the ureter from inside the bladder as already described.

In some cases when the ureter is isolated it is found to be dilated. This need not deter the surgeon from proceeding with the implantation provided the patient has not shown symptoms of severe kidney infection. Unfortunately the patient may not reach the surgeon until signs and symptoms of renal infection are well marked—pyuria, pyrexia, and pyelonephritis, and perhaps pyonephrosis. In such cases nephrectomy is indicated unless symptoms subside rapidly under treatment with urinary antiseptics.

In four of my cases the kidney has had to be removed because pyonephrosis had developed. It has been indeed a Delian sacrifice and has led me to urge that these cases should be dealt with early, when there is much more likelihood that success will follow attempts at catheterising the ureter; operation, if necessary, will be easier than at a later date and the kidney will probably be saved. I have been able to pass a ureteral catheter on one patient comparatively easily when the fistula had only been present for a week and my colleague, Mr. E. W. Riches, has had a similar experience. Cure followed in both cases, though perhaps cure should not be attributed solely to this intervention as the leakage is sometimes only temporary. I have already mentioned cases in which I was successful in this manner and in one of these it was several weeks after Wertheim's operation. I still think, however, that the sooner the attempt is made after the development of the fistula the more likely it is to be successful. If the attempts to pass a ureteral catheter fail, operation for implantation of the ureter should not be proceeded with at once as the leakage may cease spontaneously, but operation should not be delayed more than a few weeks.

Conclusions

My experience leads me to the following conclusions: 1. All uretero-vaginal fistulæ should be dealt with as soon as possible after being diagnosed. 2. In the first place prolonged and even repeated attempts should be made to catheterise the ureters. 3. On the injured side obstruction is always found to the passage of the ureteral catheter when the fistula has been present for any length of time. 4. If catheterisation fails the implantation of the proximal end of the ureter into the base of the bladder by an intravesical operation gives the best prospect of cure. 5. This implantation can be successfully carried out if the case is seen early, but after Wertheim's operation it becomes increasingly difficult as time passes and dense scar tissue develops. 6. In the event of failure to complete the graft by an intravesical operation the peritoneal cavity should be opened, the ureter isolated, and the grafting operation begun from outside and completed from inside the bladder. 7. In seriously infected cases the best procedure is nephrectomy through a lumbar incision.

The cure of this unfortunate disability may require all the skill, patience, tact, and determination to succeed with which the surgeon may be endowed. When success attends his efforts he will receive deep gratitude from the patient who has been relieved of a condition which was making life almost unbearable. If the surgeon has succeeded in curing the patient without the loss of a kidney he will in addition have the satisfaction of knowing that he has left her not only relieved of her distress but still endowed with her full renal efficiency.

TREATMENT OF PUERPERAL FEVER BY ANTISTREPTOCOCCAL SERUM

SOME NEW EVIDENCE AND A RETROSPECT

BY LEONARD COLEBROOK, M.B. Lond.

MEMBER OF THE SCIENTIFIC STAFF OF THE MEDICAL RESEARCH COUNCIL; HONORARY DIRECTOR, BERNHARD BARON MEMORIAL RESEARCH LABORATORIES, QUEEN CHARLOTTE'S HOSPITAL, LONDON

FOR 40 years antistreptococcal sera have been undergoing clinical trial all over the world for the treatment of puerperal fever. They are still very extensively used, but no agreement has been reached by clinicians as to their value. Most observers have seen the occasional patient whose temperature dropped in dramatic fashion following the administration of antistreptococcal serum (possibly a "protein shock" effect, since this has sometimes happened with an infection which was not due to streptococcus); much more often they have seen the fever remit for a few hours only and the disease continue as before. It is not difficult to understand these discordant results and the many undoubted failures of serum therapy. The term "puerperal fever" covers a very wide range of pathological conditions—from localised infections of the genital tract, parametric cellulitis, and thrombophlebitis, to generalised peritonitis, "septicæmia" with or without metastatic foci, and endocarditis.

Critical judgment of the effect of any treatment will of necessity be very difficult in many of these conditions, for some of them—e.g., the infections which remain localised to the genital tract—carry a very high spontaneous recovery-rate (nearly 100 per from inside the bladder. The surgeon need not hesitate to open the bladder during the course of an intraperitoneal operation.

If the bladder is opened and the ureter stitched in place from inside the viscus plenty of room can be left for the graft by leaving a gap below the suture line and passing a small drainage-tube through the posterior wall of the bladder into the retro-vesical tissues. The site of entry of the graft on the outside of the bladder can then be made extraperitoneal by suturing the pelvic peritoneum carefully over it.

If the bladder is not opened at the time and the implantation of the proximal end of the ureter is completed from outside the bladder the graft must generally be so closely sutured in position in order to make the junction absolutely water-tight that it is liable to become narrowed. If the implantation has been carried out in this way the graft should be kept under observation for some months and the opening of the ureter examined at intervals through a cystoscope. In this way any threatened contraction of the orifice, with the danger of damage to the kidney by obstruction and consequent increased risk of infection, can be recognised and dealt with either by dilating the orifice or, if necessary, by opening the bladder and improving the graft.

The surgeon may be labouring under the handicap that he is reluctant to call attention to the accident, but the interests of the patient demand that the graft should be kept under observation, and therefore the position must be faced and explained.

Treatment of Uretero-vaginal Fistula

I now pass to a discussion of the treatment of uretero-vaginal fistula. This may develop if the ureter has been cut and the injury has not been repaired, or if the blood-supply of the ureter has been so interfered with as to lead to sloughing of the lower end, or if the ureter or part of it has been included in a ligature or suture.

When it is noticed that there is a leakage of urine from the vagina the surgeon has first to ascertain from what part of the urinary tract the leakage is taking place.

First of all he must satisfy himself that the urine is not coming from the bladder. This is not so easy as one might expect. By careful observation and by the injection of coloured fluids into the bladder and ascertaining if any of the fluid finds its way into the vagina this point is however eventually cleared up. Being satisfied that the leakage is not from the bladder the surgeon must next ascertain from which ureter the urine is escaping. Fortunately he may easily get a very helpful clue to guide him in this investigation, for cystoscopy and the passage of a ureteral catheter may soon reveal the side on which the injury has been inflicted. The injured ureter is always obstructed whether it be completely divided or not. There is always obstruction to the passage of a catheter on the side of the fistula if it has been present a few weeks. This clue generally leads quickly to a definite diagnosis in cases following hysterectomy for fibroids, but in cases following Wertheim's operation the position is complicated by the fact that both ureters have been so disturbed and are embedded in such dense scar tissue on the floor of the pelvis that it is often difficult to pass a catheter into either ureter.

Eventually however—perhaps only after several attempts and with the use of very rigid ureteral catheters or bougies, reinforced with metal—a passage is found up one ureter while the other is found to be impassable. The side on which the obstructed ureter is found indicates the side on which the fistula is present.

In spite of the difficulties we may have to contend with in order to be absolutely sure on which side the lesion is situated, we are indeed fortunate compared with our forbears. A reference to Sir Henry Morris's Hunterian lectures delivered at the Royal College of Surgeons a short 36 years ago makes one realise the great advantages under which we work to-day. In seriously infected cases the best procedure is nephrectomy through a lumbar incision.

The cure of this unfortunate disability may require all the skill, patience, tact, and determination to succeed with which the surgeon may be endowed. When success attends his efforts he will receive deep gratitude from the patient who has been relieved of a condition which was making life almost unbearable. If the surgeon has succeeded in curing the patient without the loss of a kidney he will in addition have the satisfaction of knowing that he has left her not only relieved of her distress but still endowed with her full renal efficiency.

TREATMENT OF PUERPERAL FEVER BY ANTISTREPTOCOCCAL SERUM

SOME NEW EVIDENCE AND A RETROSPECT

By Leonard Colebrook, M.B. Lond.

MEMBER OF THE SCIENTIFIC STAFF OF THE MEDICAL RESEARCH COUNCIL; HONORARY DIRECTOR, BERNHARD BARON MEMORIAL RESEARCH LABORATORIES, QUEEN CHARLOTTE'S HOSPITAL, LONDON

For 40 years antistreptococcal sera have been undergoing clinical trial all over the world for the treatment of puerperal fever. They are still very extensively used, but no agreement has been reached by clinicians as to their value. Most observers have seen the occasional patient whose temperature dropped in dramatic fashion following the administration of antistreptococcal serum (possibly a "protein shock" effect, since this has sometimes happened with an infection which was not due to streptococcus); much more often they have seen the fever remit for a few hours only and the disease continue as before. It is not difficult to understand these discordant results and the many undoubted failures of serum therapy. The term "puerperal fever" covers a very wide range of pathological conditions—from localised infections of the genital tract, parametric cellulitis, and thrombophlebitis, to generalised peritonitis, "septicæmia" with or without metastatic foci, and endocarditis.

Critical judgment of the effect of any treatment will of necessity be very difficult in many of these conditions, for some of them—e.g., the infections which remain localised to the genital tract—carry a very high spontaneous recovery-rate (nearly 100 per cent.); while in others—e.g., fully generalised peritonitis and endocarditis—it is hardly to be expected that any therapeutic agent could overtake the infection. Moreover, these varied pathological conditions are now known to be produced by very different microbes. The hæmolytic streptococcus is responsible for about half of them; anaerobic and other types of non-hæmolytic streptococci, *B. coli*, staphylococcus, and other organisms are responsible for the rest. There is no doubt (vide Table, p. 1087) that during all these 40 years antistreptococcal sera have very often been employed in circumstances which did not allow of a *specific* curative effect.

The sera themselves have varied considerably. For about 30 years following Marmorek's[1] work (1895) most workers aimed at producing a serum which was primarily *antibacterial*—i.e., one which would control the invasion of the tissues by the cocci. The possibility—and desirability—of producing an *antitoxic* serum was, however, not lost sight of (Marmorek, Aronson,[2] 1902), but the earlier attempts in this direction were not very successful. Since the war recognition of the fact that an exotoxin of the hæmolytic streptococcus ("Dick toxin") is produced in the human body—during scarlet fever, at any rate—and that this exotoxin can be neutralised, both in vitro and in vivo, by a highly antitoxic serum, has stimulated the hope that better therapeutic and prophylactic results might be achieved by such a serum than had been obtained with the antibacterial sera. The selection of good toxin-producing strains of streptococci for the immunisation of the horses, and the improvement of technical methods for the concentration of the antitoxic fraction of the serum, have given us sera of much greater potency than those of earlier days, and these sera have been extensively employed in the treatment of puerperal fever for the past ten years. Many reports of individual cases, or of very small series, have been published, but these are of very little evidential value. On a broad view it may be said that those who have had most experience have been least convinced as to the efficacy of these sera. An analysis of a large series of cases, treated and untreated, by Benson and Rankin[3] will be referred to later.

On the hypothesis that the toxins of puerperal fever strains might differ somewhat from those of scarlet fever, some laboratories have prepared sera from toxigenic puerperal fever strains.

Warnekros, Louros, and Becker[4] reported 200 cases of puerperal fever treated with such a serum without a death. The cases are described as severe (*schwere*) but the clinical data given are extremely scanty. We are not told whether there were any cases of peritonitis nor how many of septicæmia (hæmolytic streptococci in blood culture); nor indeed how many cases were infected by that microbe. Nor is there any estimate of the recovery-rate in a comparable series of unselected cases not treated by serum. From the fact that 4 of the 6 patients whose temperature charts are reproduced (presumably among the most severe) are stated to have had *no microbes in the blood*, while the 2 remaining cases grew respectively three and five colonies from the blood, it seems probable that a large proportion of the cases presented merely a localised infection which normally carries a recovery-rate of approximately 100 per cent.

In 1928 Gaessler[5] reported a further 400 cases from the same clinic with 20 deaths; 299 of his cases were admitted with little or no fever on account of difficult labours but subsequently became more or less febrile. In this series, as in the former, there was no distinction between cases infected by hæmolytic streptococci and those which were not, and the very meagre clinical data do not permit of any judgment as to the effects of the serum. Later reports do not seem to support these first claims to success.

Still more unsatisfactory as a statistical study is the analysis by Lash[6] (1929) of 57 cases treated with a similar serum made from puerperal fever strains. The death-rate among these cases was 32 per cent., but this compared favourably with that of a control group (treated in other ways) of 13 selected cases which showed a death-rate of 61 per cent. Fortunately details are given of these control cases, and it is seen that they comprise 8 cases of septicæmia and 7 of "peritonitis or beginning peritonitis"—scarcely a representative sample of ordinary puerperal infections.

In 1929 H. Vincent[7] introduced a "new" serum which has been extensively used in France. The method of its manufacture has not been disclosed, but there seems no reason to suppose that it rests on any new principle. No evidence has been given that it can either prevent or cure an infection by hæmolytic streptococci in animals, but in a recent paper Vincent[8] (1934) has claimed that by the use of enormous doses (1300 c.cm. in one child) no less than 180 (82·5 per cent.) of a series of 218 cases classed as "septicæmia and meningitis" have been cured. This remarkable *claim demands careful examination.* Such examination shows that there has not been personal observation of the cases. They have been collected from the numerous published reports of the medical press of France and other countries and of reports of cases sent to him privately. The published reports deal almost invariably with one or occasionally two cases of recovery, and they attribute that recovery unequivocally to the serum even when many large doses were required before the temperature fell. Frequently other forms of treatment were *employed at the same time.* These *individual* case reports tell us nothing at all about other cases treated who have not recovered.

In assessing the value of such evidence I think one should not forget that many medical men will publish individual successes while few will broadcast failures. It might well be that if *all* the cases of "septicæmia and meningitis" treated by this serum were faithfully recorded the result would be very different. Again, there is some doubt as to the sense in which Vincent uses the words "septicæmia and meningitis." He does not tell us categorically in how many cases hæmolytic streptococci were grown from the blood, nor in how many from the cerebro-spinal fluid, but he does *mention in a footnote that some* cases were included although their blood culture was negative. His claim that the recovery of the 180 cases was due to serum and not to "natural causes" appears to rest, however, on the summary statement that "Le septicémie à streptocoques comporte un pronostic fatal" (1929).*

That statement does not agree with my personal experience of hæmolytic streptococcal septicæmia (with positive blood culture). With Dr. R. Hare I[10] have reported (1934) 19 such cases (excluding cases of generalised peritonitis) observed during the years 1928–33 which showed a *recovery-rate* of 41 per cent.; and in a further series of 15 such cases observed during 1934 at Queen Charlotte's Hospital no less than 11 have recovered (73·3 per cent.). Seven of these 15 cases gave a positive blood culture on more than one occasion, and five of the seven recovered. In none of these cases was specific treatment used. The recovery-rate of 73 per cent. is probably quite unusual, but *it serves to* show how cautious one should be in attributing recovery in septicæmia to any particular remedy.

My impression after a careful study of these clinical reports—and of many which preceded them—is that none of them justify the conviction that anti-streptococcal sera have really shown an indubitable effect upon the puerperal infections by hæmolytic streptococci. (I am purposely excluding scarlet fever from this survey, partly because I have no experience of it, and also because the rationale of treatment by an antitoxic serum in that disease is on quite a different footing.) If such a curative effect is to be clearly demonstrated in the human subject, it must be by application of the treatment to large groups of cases known to be infected by hæmolytic streptococci, and by critical comparison of their records with those of cases similarly infected but untreated. Both groups must be under the direct observation of the same individuals and the bacteriological data should be obtained in the same laboratory.

---

* In a later paper, 1934 (*b*), Vincent[9] admits that spontaneous recoveries from streptococcal septicæmia do occur but that they are "très exceptionelles."

Investigations of this kind carried out for the first time during the last few years will now be described.

Benson and Rankin (1933) have reported upon 114 puerperal cases observed in Edinburgh. Half of them had received serum and half had not. The two groups comprise all the cases from whom a positive blood culture (hæmolytic streptococcus) was obtained during a period of several years. (It is important to note, however, that many of the serum-treated cases were only found to be "blood positive" at some period *after* the commencement of serum treatment.—Personal communication from Dr. Benson.) In 28 per cent. of them the treatment was commenced within 48 hours of the onset of fever. Of the 57 serum-treated cases 37 received scarlet fever antitoxin and 20 "puerperal antistreptococcus serum" (which also contained some antitoxin). The authors state that both sera were manufactured by Messrs. Burroughs Wellcome and Co. In 74 per cent. of the cases the serum was given intravenously as the makers recommend. The mortality-rate in the 57 serum-treated cases was 75 per cent. as compared with 68 per cent. in the control group. In view of the "several days of misery in the form of serum sickness," the great expense (nearly £300 for the 57 patients) and the absence of any evidence that the treatment had any beneficial effect, the authors recommend that the giving of serum "faute de mieux" ought to be discontinued.

Experience of Serum-treated Cases at Queen Charlotte's Hospital

Comparison of 69 *cases treated with antistreptococcal or antiscarlatinal* (*antitoxic*) *serum before admission to Queen Charlotte's Hospital with other cases not so treated* (1930–34).

CASES TREATED BY SERUM

Infected by hæmolytic streptococci	40 (58 per cent.)
Not infected by hæmolytic streptococci ..	29 (42 „ „)

ALL CASES OF PUERPERAL PYREXIA ADMITTED TO HOSPITAL

Infected by hæmolytic streptococci	60·8 per cent.
Not infected by hæmolytic streptococci ..	39·2 „ „

DEATH-RATE OF THE SERUM-TREATED CASES AND OF THE CASES WHO HAD NO SERUM

—	Cases	Deaths	Case-mortality (per cent.)
All cases treated with serum before admission	69	21	30·4
All cases who had no serum ..	932	108	11·6
Hæmolytic streptococcus cases— Treated with serum	40	18	45·0
Treated without serum ..	346	70	22·3

Antistreptococcal sera have not been used at the Isolation Block of Queen Charlotte's, but 69 cases during the last four years had been given serum before admission. Most of them were sent in by private doctors and they came from all parts of the Greater London area.

Certain data obtained from the records of these 69 cases—and of the cases who received no serum—are shown in the Table.

COMMENTS ON THE TABLE

(1) It is unfortunately not possible to give complete and entirely reliable data as to the exact kind of serum used in every case, its amount, or the route by which it was administered, because there was often difficulty in getting all these details from the doctor who sent in the case. So far as the records serve they show that the serum was always derived from laboratories of good repute; that 39 cases got "antistreptococcal serum" and 30 scarlatinal (antitoxic, concentrated) serum. One case had both. Thirteen cases had more than one dose. The amount of serum varied from 10 c.cm. to 140 c.cm. In most of the cases it was given intramuscularly.

(2) Since the 69 cases were treated by serum before admission to the hospital it is not possible to describe their condition at the time when the treatment was begun. In about 75 per cent. of the cases the first injection was given within 48 hours after the onset of fever—often within 24 hours. After admission to the hospital all cases were treated on precisely the same lines. Glycerin was usually instilled into the uterus several times daily for the first few days and the patient's strength maintained by good feeding and nursing. In the great majority no specific treatment of any kind was used.

(3) It will be seen that over 40 per cent. of the cases treated by serum were not infected by hæmolytic streptococci and were therefore subjected to the risk of serum sickness without any prospect of a specific immunising effect.

(4) The mortality-rates for the 69 cases treated by serum and for all cases who had no serum show a very big difference, but it would be a mistake to attach much importance to this, because these two groups are obviously unsatisfactory statistical material. Both include many cases not infected by hæmolytic streptococci and also a certain proportion of cases in which the fever was really of extra-genital origin—e.g., cases of urinary infection, mastitis, bronchitis, and so forth. It is of interest to note in passing, however, that an examination of the published records of similar unselected cases of puerperal infection by a committee of the American Gynecological Society [11] in the early days of serum treatment (1899) gave very similar figures: 352 serum-treated cases showed a mortality three to four times as high as 138 cases which had no serum. The committee rightly recognised that the data were not entirely reliable and did not therefore permit of very emphatic statement of conclusions. Nevertheless it ventured the opinion that more patients were dying from the treatment than from the disease.

(5) The figures that merit most consideration are, of course, those showing the mortality-rates in the two groups infected by hæmolytic streptococci. Clearly it is difficult to deduce from them that the treatment by serum had any beneficial influence upon the infections—and this in spite of the fact that in 75 per cent. of the cases serum was given within 48 hours of the onset of fever—often indeed within 24 hours.

The important question remains, Did the serum actually, as the figures suggest, contribute to the unusually high death-rate among the 40 cases? This is such a serious issue that the data demand the most critical scrutiny.

I have considered the following possible sources of fallacy :—

(*a*) *That serum was given only to the cases who seemed most gravely ill.*—This consideration may well have been operative in a small number of the cases but not, I think, in a large proportion of them. My reason for that opinion is as follows : it is well recognised by all who have much experience of puerperal fever that the cases most gravely ill during the first week are those infected by hæmolytic streptococci. If serum had been reserved for these most severe cases one would expect to find a very high percentage (not less than 80 per cent.) of infections by hæmolytic streptococci among the 69 cases so treated. But only 58 per cent. were so infected—a figure actually a little lower than that for all cases admitted to the hospital. No less than 29 of the 69 cases, although they were given serum, had not an infection by hæmolytic streptococcus, and, as is usual in such cases, these 29 cases carried a low mortality-rate (10 per cent.). Moreover, a survey of the records of the 40 hæmolytic streptococcus cases treated by serum shows quite clearly that many of them were never gravely ill.

In my opinion therefore we must conclude that the whole 69 serum-treated cases represent just an average sample of febrile disturbances in the puerperium ; and that most of them were given serum because they happened to be in the care of a medical man who believed that as soon as a woman developed fever in the puerperium it was best to employ that remedy. Even, however, if we suppose that 5 of the 40 hæmolytic streptococcus cases were given serum because the clinical condition was judged to be unusually serious, and that all the 5 died, *there still remains a mortality-rate of 37 per cent. for the* other cases whose selection was probably not determined by this special consideration.

(*b*) *That the 40 serum-treated cases were admitted on the average somewhat later than those who had no serum—and for that reason did not gain such benefit as may accrue from the routine treatment and specialist care in this hospital.*—It has been our experience that early admission—particularly of the cases infected by hæmolytic streptococci—is definitely correlated with a high recovery-rate. On working out the time of admission of the serum-treated and other cases, however, it does not appear that this consideration can have influenced the mortality-rates shown in the Table. The 69 serum-treated cases were admitted on the average 7·8 days after labour ; the 40 hæmolytic streptococcus cases 8·0 days ; the 18 fatal hæmolytic streptococcus cases 7·8 days ; and 76 control cases, consisting of 19 consecutive cases chosen at random from each of the four years, 7·8 days.

(*c*) *That many of the infections among the 40 serum-treated cases had occurred in epidemics or during periods when the prevalent infections were of an unusually severe type.*—Actually only 4 of the 40 serum-treated cases originated in small epidemics (and 2 of them recovered). Both serum-treated and control groups were made up chiefly of sporadic cases spread over the four years. The mortality-rate among the 346 cases infected by hæmolytic streptococci never rose above 28 per cent. for any one year.

My opinion, after full consideration of these possible fallacies, is that the greatly increased mortality-rate in the serum-treated cases was due either to the serum having exerted an unfavourable effect—turning the scale against their recovery—or to the operations of chance. Choice between these alternatives is not easy. On the one hand, it is obvious that very many and very large doses of serum have been repeatedly given to human beings without apparent harm. On the other hand, evidence is not lacking which indicates that the injection of a foreign serum may sometimes be definitely prejudicial to infected human beings and animals. A. Jousset[12] (1924) and P. Courmont[13] (1934) have emphasised these adverse effects in connexion with experimental tuberculosis (guinea-pigs) and with phthisis in man.

The most striking evidence relating to streptococcal infections is that of Penfold and Butler[14] (1932), who observed that both normal horse serum and antistreptococcal sera, given to mice at the same time as a dose of living streptococci, would sometimes hasten the death of the animals. The conditions in the infected human subject under treatment by serum are admittedly quite different from those of the mouse experiments and it does not therefore follow that the therapeutic sera will necessarily exert a similar effect in the two cases, but, until we have more understanding of the mechanisms involved, that possibility cannot be ignored. Pointing in the same direction is the recent warning by B. Schlesinger[15] (1935) against the danger of giving antistreptococcal sera to children with acute rheumatism which in his experience is not infrequently "reactivated" by such treatment.

All this evidence, taken together with the well-known, but little understood, "toxic" effects of horse serum, ought, I think, to be taken into account before we subscribe to the dictum so often expressed that "*a dose of serum can at any rate do no harm.*" Can we be sure that an agent capable of causing such profound disturbances as those associated with anaphylaxis, serum sickness, and agglutination of red corpuscles (the extreme degree of incompatibility between horse serum and human reds does not seem to have been generally recognised), will not sometimes have an adverse effect upon the complex mechanisms concerned in immunity to infective diseases ? I would suggest that our view of serum therapy has in the past been somewhat unbalanced. We have focused attention too exclusively upon its antitoxic or antibacterial qualities and rather lost sight of the "toxic" potentialities which have to be set off against them. The possible benefits of passive immunisation probably must always be paid for. Sometimes, as in the case of diphtheria antitoxin, the price may be well worth while—in other cases, as perhaps in the case of antistreptococcal serum, it may be too heavy.

At Queen Charlotte's, if we had given serum to all cases infected by hæmolytic streptococci, and if they had had the same death-rate as in the 40 cases so treated before admission (vide Table), there would have been approximately 86 more deaths than actually occurred during the years 1930–34.

Experimental Basis of Treatment by Antistreptococcal Serum

It would not be profitable to set out in full the results of a critical survey of all the experimental work published in connexion with antistreptococcal serum, because so many points are left in doubt and require reinvestigation in the light of new knowledge about the group of hæmolytic streptococci. The following brief summary and references may, however, be useful :—

PROTECTION EXPERIMENTS

(1) By the immunisation of horses, rabbits, and sheep, sera have been obtained which, when given some hours in advance of the infecting dose, would protect mice and rabbits against 1000–100,000 M.L.D. of the strain used for immunisation (Marmorek, Bordet,[16] Aronson, Neufeld,[17] Simon,[18] Dochez, Avery, and Lancefield,[19] Yoshioka,[20] Lancefield and Todd[21]).

(2) It appears that these highly effective sera have only been produced with streptococcal strains of exceptional virulence, resulting from frequent passage through animals.

(3) Some of these protective sera were active against other strains of hæmolytic streptococci than that used for the immunisation of the horses (Sommerfeld,[22] Neufeld (1903), Simon) ; and it is possible (although not proven) that these other strains were sometimes of different serological type. On the other hand, the work of Dochez,

Avery, and Lancefield strongly suggests that the protection afforded by such sera is strictly type specific.

(4) It is not clear that the protective sera thus obtained by immunisation with highly virulent "passage strains" have ever been effective against strains of moderate or low virulence such as are habitually isolated from human infections—e.g., puerperal fever, surgical sepsis, &c.

(5) The mechanism of protection by the highly active sera has not been adequately established, but the work of Bordet, and particularly that of Neufeld and Rimpau,[23] seems to show that their capacity to render the very virulent streptococci susceptible to phagocytosis ("bacteriotropin effect") is a very important factor.

(6) Sera produced by the injection of toxigenic cultures of hæmolytic streptococci, or by filtrates of such cultures, into animals, are capable of neutralising that toxin both in vitro and vivo (Parish and Okell,[24] Hartley,[25] Pulvertaft[26]). When a potent antitoxic serum is injected into rabbits in advance of a large dose of an avirulent culture containing such toxin, the life of the animals is prolonged, or sometimes saved (by virtue of the neutralisation of the toxin), but infection of the tissues is not prevented (Parish and Okell). (It may be mentioned also that the active immunisation of human beings by Dick toxin does not render them immune to infections by hæmolytic streptococci—as judged by the incidence of tonsillitis among the immunised staffs of fever hospitals (Benson and Rankin,[27] 1934).)

(7) The commercial sera issued in recent years have at best only a very slight protective action against hæmolytic streptococci freshly isolated from acute septic infections of man even when they are given some hours in advance of the infection. When given at the same time as the infecting dose of streptococci they occasionally prolong the life of the test animals by a few days, more often they show no effect at all, and sometimes they definitely hasten death (Penfold and Butler).

CURATIVE EXPERIMENTS

Besredka [28] (1904) and Aronson (1905) record that a highly protective serum obtained by the immunisation of horses with a very virulent "passage strain" was able to overtake a rapidly fatal septicæmic infection of mice if it was given within 12–24 hours after the infecting dose of homologous culture. Repetition of the serum dose was sometimes necessary. Besredka's statement is the more precise. He says that 1/40–1/400 c.cm. of serum would suffice to save mice infected 18–24 hours previously with 2000 M.L.D. of culture.

I have failed to find evidence that the commercial sera now available have the slightest *curative* effect in infected animals.

IN VITRO EXPERIMENTS

The antistreptococcal and antitoxic sera at present available have not been shown to possess any bactericidal power. Hæmolytic streptococci will grow in them. Nor have these sera any power to promote the phagocytosis of virulent streptococci (bacteriotropin effect) (R. Hare [29]).

I believe it is correct to say that most of the laboratories producing these sera do not test them at all for any antibacterial (as opposed to antitoxic) properties.

Conclusions

1. There is no trustworthy clinical evidence that the administration of antistreptococcal serum for the treatment of human infections by hæmolytic streptococci has had any specific curative effect. (A possible effect on the *toxic* manifestations of scarlet fever is purposely excluded from this statement.)

2. The evidence obtained in puerperal fever cases at Queen Charlotte's Hospital suggests that such administration may sometimes have an *unfavourable effect* upon puerperal infections by hæmolytic streptococci; and this impression is to some extent supported by the evidence of animal experiments. All our experience carries the lesson that it is in the best interest of the patient suffering from an infection by hæmolytic streptococci not to interfere with her immunising mechanisms (about which we know so little as yet) until we can be sure that such interference does not do harm.

3. Although sera have been produced which would protect animals against infection by streptococci of artificially enhanced virulence, there is no satisfactory evidence that a serum has ever been produced which would afford more than very slight protection (occasionally) against hæmolytic streptococci freshly isolated from acute human infections and of various serological types.

4. Similarly there is no evidence that any antistreptococcal serum has ever exerted a *curative* effect in animals infected by such hæmolytic streptococci freshly isolated from human infections.

5. It is a matter for regret that antistreptococcal sera should have been issued for clinical trial so long before satisfactory experimental evidence as to their curative effects in animals was available—or a strong presumption existed (from unequivocal in vitro experiments) that such a curative effect would be obtained in man. Until our knowledge of immunisation against the hæmolytic streptococci has progressed further it would seem desirable to discontinue the use of antistreptococcal sera in the treatment (and prophylaxis) of puerperal fever and "surgical sepsis."

WORTHING HOSPITAL.—The governors of this hospital, with the financial support of the borough council and the West Sussex county council, have authorised the preparation of plans for a maternity block designed as a self-contained unit with independent lighting and heating systems. Of the ten beds to be provided, half will be at the service of the borough and county councils. The building is to be planned so that the number of beds may be increased to 16. The patients will be nursed by a staff of fully qualified midwives who will be lodged and boarded on the new premises. The proposed cost is £12,000. Of this sum, £8000 is either in hand, or promised, including £1000 from each of the two councils. The accounts of the hospital for the year showed a deficit of £630, and if £2010 received from legacies had not been put into revenue the debit balance would have amounted to £2640.

FURTHER STUDIES ON THE ÆTIOLOGY OF ACUTE RHEUMATISM

By Bernard Schlesinger, M.D. Camb., F.R.C.P. Lond.
PHYSICIAN TO OUT-PATIENTS, HOSPITAL FOR SICK CHILDREN, GREAT ORMOND-STREET, LONDON
A. Gordon Signy, M.B. Lond.
ASSISTANT PATHOLOGIST AND RESEARCH FELLOW AT THE HOSPITAL; AND
W. W. Payne, M.B. Lond.*
BIOCHEMIST TO THE HOSPITAL
(From the Hospital for Sick Children and from the Children's Heart Hospital, West Wickham)

The search for a causal bacterium in acute rheumatism is at present mainly concentrated upon the hæmolytic streptococci. A direct demonstration that these organisms are constantly present in rheumatic inflammatory lesions would be convincing, but the results of different workers are not in agreement. This divergency has led to other methods of approach to the problem. In most of the recent investigations the search for bacteria in the affected tissues is abandoned and the indirect method of demonstrating immunity reactions to hæmolytic streptococci is employed.

Agglutination, complement-fixation, and precipitin reactions have all been used for this purpose (Coburn and Pauli, 1932). Even more delicate and specific are the tests for antihæmolysin (Todd, 1934; Griffiths, 1934), antistreptolysin (Myers and Keefer, 1934), and antifibrinolysin (Hadfield, Meager, and Perry, 1934). It is important to realise, however, that these immunity reactions are not specific to rheumatism but appear in the blood during convalescence from scarlet fever, erysipelas, acute streptococcal tonsillitis, and indeed after any acute streptococcal infection. Similar reactions in patients with acute rheumatism cannot then be taken to indicate anything beyond proof of a recent infection with hæmolytic streptococci.

In a previous communication (Schlesinger and Signy, 1933) we showed that it was possible to demonstrate streptococcal precipitins in the blood of rheumatic patients two to four weeks after the onset of a nasopharyngeal infection. The time at which these appeared thus corresponded to the end of the "silent period." The type of precipitin produced corresponded to the type of streptococcus responsible for the throat infection, although a certain amount of cross-precipitation occurred. Cases which relapsed with acute rheumatism gave the most marked precipitin reactions, and the question was raised whether a positive precipitin reaction might not be taken as an indication that a rheumatic relapse was to be expected. Here the matter was left to await further research into the whole question of precipitin formation following streptococcal tonsillitis.

Present Investigation

Our previous experiments were conducted with filtered saline extracts of ground-up streptococci ("endotoxin"). A natural presumption was that certain constituents of the bacterium would be found to have particularly strong precipitogenic properties. The present investigation deals with this problem, and also attempts to discover the principal factors involved, particularly in what way the reaction might be peculiar to acute rheumatism.

Of the various bacterial parts the carbohydrate fraction of the streptococcus has been consistently found to possess such poor antigenic properties that we have concentrated on the protein fractions. By the process described in the Appendix to this paper, two distinct nucleoprotein fractions were obtained—an acid and an alkaline extract—and precipitin reactions carried out with each. These extracts were derived from the following three organisms, and tests were performed with each, as far as possible in the same patient for the sake of comparison.

1. A hæmolytic streptococcus obtained from the throat of a patient with virulent rheumatism "(Carter streptococcus"), hereafter referred to as H.S.
2. A scarlet fever streptococcus, hereafter referred to as S.F.
3. A *Streptococcus viridans* obtained from the blood culture of a case of subacute bacterial endocarditis, hereafter referred to as V.

Tests were also carried out with the globulin and albumin fractions obtained, undenatured, from ground-up cocci. (See Appendix.)

In the first series of experiments 30 rheumatic patients were investigated after an attack of acute pharyngitis which was not followed by a definite rheumatic relapse. The patients' sera were tested for precipitins at intervals during a period of two or three months, using the technique described in our previous paper.

After a while it was noticed that nucleoproteins prepared from different batches of the same cultures of streptococci varied in their antigenic properties, although the technique used in their manufacture was identical. This meant that a series of comparable precipitin reactions in one patient could only be expected if the same batch of antigen were employed throughout.

PRECIPITIN REACTIONS IN RHEUMATIC PATIENTS FOLLOWING ACUTE TONSILLITIS OR PHARYNGITIS

In 9 out of the 30 cases the results obtained were considered unreliable owing to the reason just mentioned. In the remaining patients the same batch of nucleoprotein (Batch L) was used throughout in 15 cases and another batch (Batch 1A) throughout in a further 6 cases (see Table I.).

Table I.—*Precipitin Reactions*

—	Nucleoprotein.		Total.
	Batch L	Batch 1A	
Number of cases	15	6	21
Positive reactions	12	6	18
Negative reactions	3	0	3
Time of appearance following acute tonsillitis—			
(1) Between 10th and 30th day	9	3	12
(2) During 1st week	3	3	6
Final precipitin test—			
(1) Precipitin absent	10	4	14
(2) Precipitin still present ..	2	2	4

Throat cultures taken during the attack of acute tonsillitis showed the presence of hæmolytic streptococci almost invariably except in the three patients with negative precipitin reactions, from whom indifferent streptococci unrelated to the three antigens used were cultivated. The time at which precipitins appeared in the blood stream is of some interest. In

---

* All working with a grant from the Harmsworth Research Fund.

12 of the 18 cases the characteristic immunological response developed during the second and third weeks after infection. In the remaining 6, precipitins were found present very shortly after the tonsillitis, during the first week. Two opposite types of reaction were observed in this last group:—

(1) An increasing degree of precipitin formation during the four consecutive weeks following the tonsillitis (3 cases).

(2) The strongest reaction observed immediately, waning during the ensuing weeks (3 cases).

This observation and also the fact that precipitins usually disappeared in the end suggest that the reaction, although present early, was again an immunological response to the preceding tonsillitis and not an inherent property of these sera. As a rule precipitin was only demonstrable for a period of one month, but in one or two cases it persisted for several months. Occasionally a return of precipitin was noted two to three months after the tonsillitis, long after the original reaction was over and the patient's serum had been negative for some time. Such instances are not included in the analysis just given and their significance is not understood.

DETAILS OF PRECIPITATION

Reference has already been made to the varying potency of the different antigens used. Details of the individual tests which follow (Table II.) make it quite apparent that the acid nucleoprotein extract of the "Carter" hæmolytic streptococcus (HS.D.) gave the largest number of precipitin reactions. Tests with bacterial globulin and albumin showed that both components have antigenic properties, although the globulin element appeared to be the more potent. It is interesting to note that when doing skin tests with these extracts, the best reactions were obtained with the alkaline extract (HS.E.).

* Rheumatic.

Abbreviations.—H.S.= hæmolytic streptococcus (Carter). S.F.= scarlet fever streptococcus. V.= *viridans* streptococcus from malignant endocarditis. D.= acid nucleoprotein extract. E.= alkaline nucleoprotein extract. A.= albumin extract. G.= globulin extract.

+ = positive. ± = slight positive. tr. = trace.

A certain amount of cross-precipitation was observed, for positive reactions occurred with antigens other than those obtained from bacteria isolated from the throat at the time of the tonsillitis. With one exception, whenever precipitins to HS.D. or E. were found present in the patient's serum, the preceding tonsillitis had always been a hæmolytic streptococcal infection. Positive precipitin reactions with V.D. or E. antigens were not necessarily associated with a previous *Streptococcus viridans* infection of the throat. Occasionally precipitin reactions were produced by the S.F. antigen as well as the H.S. antigen.

CONTROL EXPERIMENTS

Two sets of experiments were undertaken. In the first of these the sera of different groups of people were tested against the nucleoprotein of organisms other than streptococci. For this purpose *B. coli* and *Staphylococcus aureus* were chosen, and antigens were prepared from these with the standard technique. Presumably because of the universal distribution of these organisms, positive precipitin reactions were obtained in most of the subjects tested (Tables III. and IV.). These cannot therefore be regarded as suitable controls. Nevertheless they have been included since they form a striking comparison with the negative results obtained with streptococcal antigen in normal non-rheumatic subjects.

The second series of control experiments was concerned with streptococcal precipitin reactions in different groups of individuals. It attempted to assess the relative importance of rheumatism and tonsillitis in this connexion. There were four groups as follows: (1) patients with quiescent rheumatism unassociated with acute tonsillar infection; (2) non-rheumatic subjects; (3) non-rheumatic individuals following a recent tonsillitis; (4) scarlet fever patients. The results of the experiments on these four groups have been summarised below.

1. *Control patients with quiescent rheumatism.*—A total of 13 patients were tested for precipitin reactions with streptococcal nucleoprotein, and the results were:—

Negative to H.S., S.F., and V., both to D. and E. antigens	8 cases.
Slightly positive to HS.D	4 „
Positive to HS.D	1 case.

From this it would appear that in the absence of tonsillitis streptococcal precipitin formation is neither very common nor well marked.

2. *Non-rheumatic patients (surgical cases).*—In this group 16 cases were tested:—

Negative to H.S., S.F., and V., both to D. and E. antigens	12 cases.
Slightly positive to HS.D	2 „
Slightly positive to V.D.	2 „

Non-rheumatic persons thus showed only a few slight positive reactions.

3. *Non-rheumatic patients following tonsillitis.*—When, however, another similar group of non-rheumatic patients

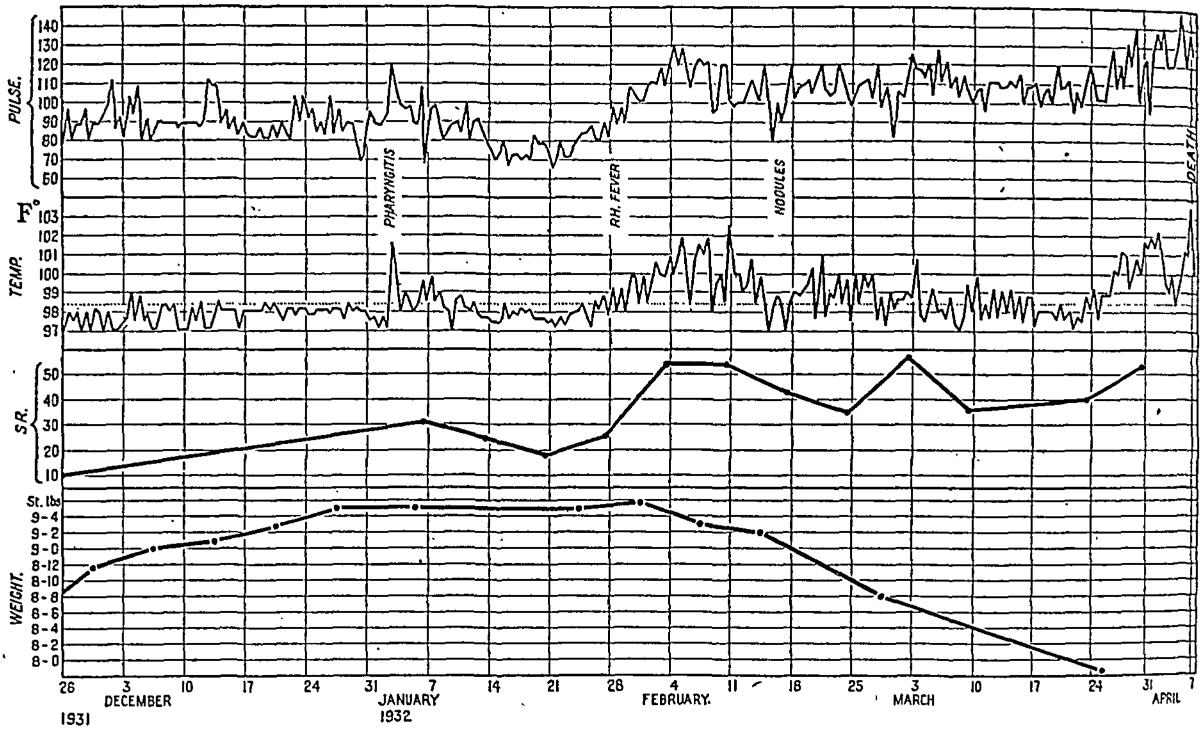

FIG. 1.—This chart illustrates various stages of a rheumatic relapse. The patient, a girl of 14 years, with old mitral endocarditis, was in a quiescent stage, afebrile, with a normal pulse-rate and steadily gaining weight. Her tonsils had been removed; nevertheless, following an acute pharyngitis and a "silent period" of three weeks, active [illegible] fever, pericarditis, and later, the appearance of subcutaneous nodules. Note the sudden increase o[illegible] (S.R.) and the synchronous rapid loss of weight until death supervened.—From "Recent Progress in [illegible]" edited by Sir John Collie, chapter on Rheumatism by Schlesinger. London. 1933.

were tested shortly after an attack of acute tonsillitis, half of them gave positive reactions at the appropriate time—though the numbers are too small for comparison. The 6 cases gave the following results:—

Positive to HS.D., SF.D., and SF.E. between 10th and 18th day (neg. 24th day) ..	1 case
Positive to SF.D. between 10th and 18th day (neg. 24th day)	2 cases.
Negative throughout	3 ,,

4. *Scarlet fever patients.*—We are indebted to Dr. Wilfrid Sheldon for the results of a series of precipitin tests performed on the sera of his scarlet fever patients shortly after the onset of the disease. In the 30 cases the results were:—

Positive to SF.D. (3 of them also positive to SF.E.)	14 cases.
Positive to HS.D. (2 also positive to HS.E.)	5 ,,
Slightly positive to HS.D.	2 ,,
Positive to HS.E. only	3 ,,
Slightly positive to V.E.	2 ,,
Negative to SF.D.	16 ,,
Negative to SF.E.	27 ,,

Thus precipitins were demonstrated in the blood of about half of these patients. Reactions with the scarlet fever streptococcal antigen were obtained frequently in this group alone, a fact that is perhaps not surprising, and lends support to the view that these reactions are largely specific.

Finally a comparison was made between the sera of rheumatic and non-rheumatic patients with and without a preceding tonsillitis in regard to precipitin formation against the globulin and albumin fractions of hæmolytic streptococci. Positive results were most often observed in rheumatic patients following tonsillitis. This is not surprising, since it is in these cases that a reaction with the unsplit nucleoprotein antigen is most frequently obtained. The results of these experiments are given in Table V.

Discussion

It has already been emphasised that precipitins to hæmolytic streptococci can be demonstrated in a number of non-rheumatic conditions. The investigations here recorded indicate that precipitin formation in acute rheumatism depends more upon the preceding tonsillitis than upon the rheumatic process itself. The sera of patients with quiescent rheumatism unassociated with a recent throat infection were almost consistently negative. On the other hand, tonsillitis in a proportion of non-rheumatic subjects was also found to provoke precipitin formation at a time and to a degree strictly comparable to that observed in rheumatic patients. Notwithstanding this, we were impressed with the more constant reactions which occurred among the latter, and it would be no exaggeration to say that rheumatic patients appear to react more strongly to acute streptococcal infections than do other people. Our researches prove no more than this. At the same time they give some indication that the various immunological responses, such as the formation of precipitin, antihæmolysin, antifibrinolysin, &c., in acute rheumatism are all probably the direct outcome of an acute streptococcal nasopharyngeal infection. It is well recognised that such an infection may be present without symptoms and thus go undetected. That it may be followed two to four weeks later by acute rheumatic manifestations is also well known (Schlesinger, 1930). In the latter event, the antistreptococcal reactions discovered in the patient's serum might be interpreted as proof that the acute rheumatism is a direct result of infection with hæmolytic streptococci. This assumption may be correct, but is not justifiable from this evidence alone.

To our minds one of the most important and interesting features of rheumatic disease is the "silent period." A clear explanation of the interval of ten to thirty days which intervenes between a rheumatic relapse and the preceding streptococcal tonsillitis would add considerably to our knowledge of the ætiology. The fact that changes in the patient's blood, such as precipitin formation, are also at their height at the end of that period and just when the relapse is to be expected must have a distinct significance. The association has been explained on an allergic basis, but the reasoning is not clear or satisfactory.

On the evidence of these serological reactions it might be assumed that the patient's immunity to streptococcal infection is at its height at the end of the "silent period." Careful inquiry, however, reveals that it is just at this time that localised inflammatory lesions are likely to occur throughout the body. This is obviously the case with regard to acute rheumatism (Fig. 1). The complications of streptococcal tonsillitis in general also point to the fact that the patient appears to be particularly vulnerable at the time when the early serological changes are at their height, that is, during the second and third weeks.

"SILENT PERIOD" IN DISEASES OTHER THAN RHEUMATISM

The four examples that will be given are otitis, meningitis, adenitis, and nephritis. Some of these disorders are frankly pyogenic in nature, but whether they can be explained as a direct extension of the original infection or need some other interpretation, the same "silent period" is found in them all. It is shortest in *otitis* following tonsillitis, being then more often a week or ten days (Fig. 2). Otitis may also follow tonsillectomy, and in this case the intervening period is usually longer.

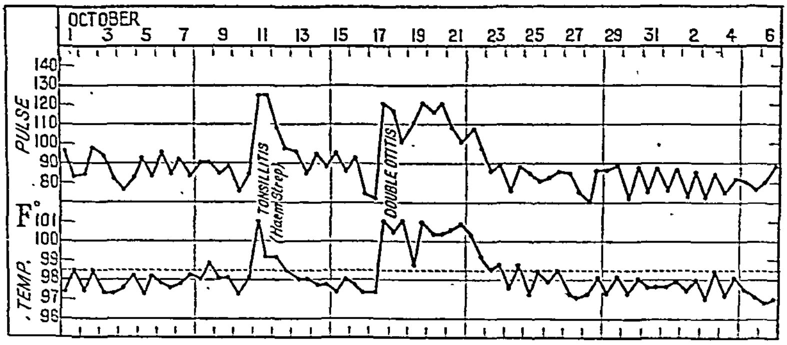

FIG. 2.—The chart in a case of streptococcal tonsillitis complicated by otitis media, demonstrating a similar although shorter silent period to that seen in Fig. 1.

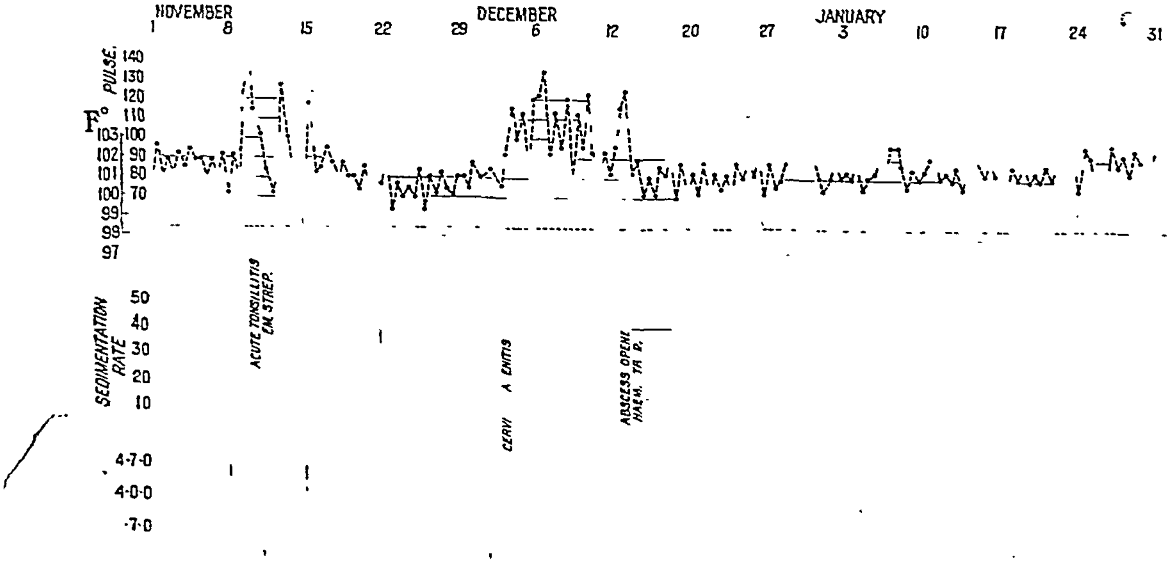
The silent period in streptococcal *meningitis* is not generally realised, but deeper inquiry into the history of such cases will almost always elicit the same story. So constant is this that it becomes almost pathognomonic of the disease. The illness begins with an acute nasopharyngeal infection, followed in about a week by an extension to the middle ear. Here the inflammation may gradually subside spontaneously or require relief by paracentesis. After this the temperature falls to normal, and the patient appears to be well on the road to recovery. The picture then changes abruptly, when three weeks from the



-. 3.—Cervical adenitis following a hæmolytic streptococcal tonsillitis with a well-marked inte onset of the otitis there is a sudden renewed pyrexia with signs of cerebral irritation. This soon gives way to evidence of frank meningitis, and the condition generally terminates fatally.

These are two examples of delayed pyogenic complications in close connexion with a primary focus of infection.

Cervical *adenitis* may either become purulent or stop short of this and heal without interference. In either event the same remarkable intervening period occurs (Fig. 3).

Nephritis following simple streptococcal tonsillitis or scarlet fever resembles acute rheumatism in being seldom pyogenic. Again there is the delay of two or three weeks before it arises. Suspecting that there might be changes in the kidneys short of actual nephritis following acute streptococcal throat infections, we have investigated 20 rheumatic patients with this point in view. In a large proportion of those examined it was found that a varying degree of albuminuria appeared in the urine, sometimes associated with red and white blood-cells, from the tenth to the twenty-first day after the onset of tonsillitis. The urine was examined daily for over a month both by heating and by the salicyl sulphonic acid test. Ten rheumatic patients without tonsillitis were also investigated as controls. In a number of these, albumin was found to be present at various times, but not persistently over a given period, and only for a day or two at a time. Among the controls the albuminuria was never associated with red or white cells in the urine. Catheter specimens were taken in a few cases from both series and the urine cultured. These were found to be sterile, and throughout the investigation streptococci were not discovered on microscopic examination of the deposits obtained by centrifuging the urine. These slight renal inflammatory changes following throat infections are not confined to rheumatic patients. De Wesselow (1932) made a similar investigation of 134 patients who were recovering from an attack of tonsillitis and found albuminuria in a considerable proportion of them.

It appears therefore that the widespread results of an acute streptococcal throat infection can be recognised both in rheumatic patients and in those who show no evidence of a subsequent rheumatic process. Some of these results may become manifest after a latent period, and at the time when the immunity response to the original infection is at its height. The tissues at that time appear to be particularly vulnerable and it is possible that this allows some as yet undiscovered cause of rheumatism to enter the body; or perhaps this state of increased susceptibility permits an already present but latent causal agent to enter into a state of activity. It is conceivable that a virus may be the answer to the problem, and we are investigating the disease further from this point of view.

Summary and Conclusions

(1) Streptococcal precipitins can be demonstrated in the blood of rheumatic patients following acute streptococcal throat infections. The most usual time of their appearance is between the tenth and thirtieth days. (2) The nucleoprotein and globulin fractions of the bacterial substance provide the best antigens for demonstrating the reaction. (3) Although the reaction seems to be most frequent and strongest in rheumatic subjects, it is not confined to them. Tonsillitis in non-rheumatic patients may give rise to the same sequence of events. (4) Rheumatic relapses are commonest from ten to thirty days after a streptococcal tonsillitis—i.e., at a time when changes in the patient's blood, such as precipitin formation—are at their height. (5) The presence of a similar "silent period" in various complications of streptococcal tonsillitis is reported and its general significance is discussed. (6) The relationship of hæmolytic streptococcal infection to acute rheumatism is reviewed, and mention is made of the possibility that the disease is caused by some additional specific factor such as a virus.

Appendix

PREPARATION OF NUCLEOPROTEIN EXTRACTS (HEIDELBERGER AND KENDALL, 1931)

Cultures of organisms obtained in a medium of glucose phosphate broth at a pH of 7·8 were centrifuged. The deposit was washed in saline and suspended in 200 c.cm. of acetone. It was then shaken mechanically for two hours, centrifuged, resuspended in the same quantity of acetone and allowed to stand overnight.

After being centrifuged again the organisms were suspended in 200 c.cm. of ether which had previously been freed from alcohol, peroxides, and aldehydes by washing with water, drying with calcium chloride, and storing in the dark over calcium chloride and sodium hydroxide pellets. The suspension was then stirred frequently for several hours, again centrifuged, and this process repeated with a fresh quantity of purified ether. A final amount was added and the mixture was allowed to stand overnight, after which it was centrifuged and the organisms were dried in vacuo over phosphorus pentoxide. The defatted cells were ground in a ball mill at room temperature until no intact cells could be observed in a smear stained by Gram's method.

The ground material was then rotated in the ball mill with a little 0·2 normal acetate buffer solution at pH 4 for 10 minutes and rinsed into about 200 c.cm. of the same buffer solution and shaken mechanically for 5–6 hours. All these operations were performed in the cold. The mixture was then centrifuged. The supernatant was saved and was tested for specific polysaccharide.

The residue in the centrifuge tube was ground in a mortar with a little chilled M/15 phosphate buffer solution at pH 6·5, and added to about 200 c.cm. of the same solution and shaken mechanically for 5–6 hours. The mixture was centrifuged until clear, and the supernatant was removed and acidified with glacial acetic acid until the resulting precipitate began to flock (Fraction D). The residue in the centrifuge tube was ground and extracted with about 200 c.cm. of water, adding enough normal ammonium hydroxide from time to time to maintain pH at 8·4—i.e., just pink to phenolphthalein. The mixture was again centrifuged and cleared as much as possible, and the supernatant acidified with 50 per cent. acetic acid until the precipitate began to flock (Fraction E). Supernatants of Fractions D. and E. were tested for carbohydrates. Fraction D. was homogenised in about 50 c.cm. of water and redissolved with the aid of chilled normal sodium bicarbonate solution which had been neutralised to pH 6·8 by cooling and cautiously adding glacial acetic acid. Care was taken to leave Fraction D. acid to litmus.

Fraction E. was similarly treated, using ammonium hydroxide instead. The pH of Fraction E. should never overstep pH 8·5. After reprecipitation, Fraction D. was dissolved in neutralised normal sodium bicarbonate, centrifuging off any insoluble residue, if necessary. To this solution sufficient 5 per cent. phenol was added to make 0·5 per cent. final concentration. Fraction E. was redissolved in a minimal amount of N/10 NaOH and centrifuged. To the residue more N/10 NaOH was added and the mixture centrifuged, the supernatants being saved and carbolised as in Fraction D. The total nitrogen was estimated in both solutions D. and E. by a micro Kjeldahl method and diluted for use to a concentration of 20 mg. of nitrogen in 100 c.cm.

Both these fractions consist of nucleoprotein. Fraction E. is relatively stable, but Fraction D. is very easily broken down into simpler substances, and even slight increases in the pH of the solutions are capable of bringing this change about. It was found almost impossible to maintain the exact pH of the neutralised sodium bicarbonate solution owing to loss of CO_2 with slight rises of temperature or even rough handling. This is the cause of the varying potency of the D. fragment. In regard to the bacterial fragments it would seem that the less the protein complex is broken up, the greater is its antigenic power. This is also shown by the larger moleculed globulin fraction having a greater antigenic power than the smaller moleculed albumin fraction.

PREPARATION OF ALBUMIN AND GLOBULIN FRACTIONS (GOUGH, 1933)

Twenty litres of a 24-hour culture of hæmolytic streptococci, grown in glucose phosphate broth, was centrifuged and the deposit desiccated over concentrated sulphuric acid in vacuo for two days. The dried organisms were then transferred to a ball mill and ground until no intact organisms could be seen in a stained smear.

The contents of the ball mill were then extracted with 500 c.cm. of distilled water by shaking for 2–3 hours and then centrifuged and the supernatant fluid removed. The deposit was again shaken with 200 c.cm. of water and recentrifuged, and the supernatant fluid removed and added to the first fluid. This was repeated until only a little insoluble material was left. The supernatant fluids were then saturated with ammonium sulphate. After a short time a curd appeared, consisting of the precipitated proteins. The whole was filtered and the curd saved. This greyish curd was washed into about 100 c.cm. of distilled water, shaken vigorously, and refiltered. This process was again repeated, and the filtrate was then half saturated with ammonium sulphate. A white flocky precipitate formed; the whole was centrifuged and the precipitate, the globulin fraction, was dissolved in a minimal amount of water. The supernatant fluid was completely saturated with ammonium sulphate, and the precipitate, the albumin fraction, was redissolved in a minimal amount of water. Both the globulin and albumin fractions were dialysed in collodion sacs until no more ammonium sulphate was present.

We are indebted to Dr. D. N. Nabarro, director of the pathological department at the Hospital for Sick Children, for his help and encouragement in these researches. Our thanks are also due to Dr. C. R. G. Barrington and the nursing staff at West Wickham for their valuable assistance, and to Mr. G. W. Cecil for his technical aid.

BIRMINGHAM GENERAL HOSPITAL.—A further financial improvement is to be noted in the report of this hospital. The contributory association has increased, and not only has ordinary expenditure been met out of ordinary income, but a large proportion of extraordinary expenditure has also been provided from the same source. Substantial legacies have made it possible further to increase the reserves. The income was £86,482, as against £82,026 in the previous year, and the number of in-patients was 8369 (an increase of 63 on last year). The total number of new out-patients was 59,400, as against 56,459 in 1933.

CLINICAL TRIALS WITH A NEW ANTITYPHOID SERUM

By C. J. McSWEENEY, M.D. N.U.I., M.R.C.P. Irel., D.P.H.

MEDICAL SUPERINTENDENT, CORK STREET HOSPITAL, DUBLIN

In September, 1934, a new antityphoid serum was obtained from Dr. Felix, of the Lister Institute, London, for experimental purposes. The serum was unconcentrated and contained antibodies to both the "O" and the "Vi" antigens to a titre of 1 in 40,000 and 1 in 400, respectively. It was decided to give this serum to every other case admitted, alternate cases receiving equivalent amounts of normal horse serum. This plan was adhered to for the first 8 cases, but when the beneficial effects of antityphoid serum were observed, it became difficult to withhold it from subsequent severe cases. Consequently the experimental group, to date, comprises 8 cases, whereas the control group numbers only 4. Of the 8 patients receiving antityphoid serum all except one recovered, the exception being a case who perforated some days after receiving 10 c.cm., a dose we now know to have been far too small. One of the 4 controls also died, another developed a carditis which prolonged convalescence, and two children who had mild illness pursued a normal course towards recovery, though one continued to have liquid motions for six weeks from onset.

Before summarising the main points of interest in the individual cases comprising this small series, it should be mentioned that every case of proved infection with *B. typhosus* admitted to hospital since last September was either given antityphoid serum or used as a control. The intramuscular route was used except in Case 9, when some of the serum was given intrathecally. None of the 12 patients had received T.A.B. vaccine or had suffered from a previous enteric infection. The controls were actually alternate cases and were not selected. The cases here referred to were treated independently of the Palestine experiment,[1] Dr. Felix deliberately withholding his findings so that the serum might be investigated without any preconceived ideas as to its effects.

In the following notes the expression "clinically definite" means that the patient had many or all of the classical symptoms and signs of enteric infection—viz., insidious onset; steadily rising temperature in the first week, remaining remittent later, and subsiding by lysis; disproportionately slow pulse; headache (giving way later to delirium); epistaxis; bronchitis; tumid and perhaps tender abdomen; some abnormality of the digestive system, usually diarrhœa; enlargement of the spleen; rose spots; and the appearance of the diazo reaction in the urine between the 8th and 12th day of the fever. Toxæmia was graded according to severity by a system of pluses. Toxæmia graded "+" corresponds to that met with towards the end of the first week of the disease in an average case, the grading "++" indicates a degree similar to that experienced during the "stage of advance" in the average case, whereas "+++" connotes a degree equivalent to that found quite early in the very severe cases, or more commonly, in the "typhoid state" into which the average case may drift towards the end of the third week.

It is unfortunate that there is no precise method of assessing, and of graphing, toxæmia, for the effect of the serum in reducing it was much more striking than is apparent from a study of the temperature charts, some of which are reproduced below.

CASE RECORDS

CASE 1.—John A., aged 17½ years, admitted on 8th day of disease. Clinically a definite enteric infection; Widal positive on 9th day. One of three members of the same family treated. Was first case in series to receive antityphoid serum, a single dose of 10 c.cm. being given on 17th day. Toxæmia graded "++" before serum administered. Noted as "brighter, toxæmia less" on succeeding days, but perforation suddenly occurred on 20th day. Laparotomy immediately performed revealed a large rent in the distal end of his small intestine which was sutured. Several other impending perforations in adjacent bowel noted. Patient died seven hours after operation.

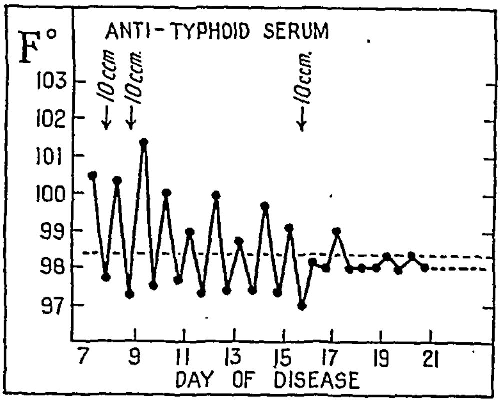

FIG. 1 (Case 3).

Comment.—Dosage of serum far too low. This was due to Dr. Felix's absence in Palestine, his advice as to dosage not being received until some weeks later, by which time we had ourselves increased it. If such a case had come under treatment in November, three doses, each of 50 c.cm., would have been given, and in the event of perforation supervening 80–100 c.cm. would have been injected into the peritoneum before closure of the laparotomy wound. This was the only fatality among the cases receiving antityphoid serum.

CASE 2.—A control. Michael A., aged 5 years, brother of John A. (Case 1), admitted in 12th day of disease. Clinically definite but, as is usual with children, a mild case. Widal positive for *B. typhosus* 14th day. Given one injection of normal horse serum (10 c.cm.) on 22nd day, on which day motions were normal. Toxæmia was noted as absent before horse serum given. Pulse-rate kept over 100 until 32nd day of disease.

CASE 3.—Mrs. A., aged 45, mother of the two previous patients, admitted on 7th day of disease. Clinically an enteric infection. *B. typhosus* grown from the blood. Toxæmia on admission graded "++." After two doses of serum (each 10 c.cm.) given on 8th and 9th day, pyrexia at a lower level, and toxæmia "+" (Fig. 1). Final dose of 10 c.cm. of antityphoid serum on 16th day seemed to abort the disease, toxæmia being noted as absent within next 24 hours. Motions normal on 23rd day.

Comment.—This woman was quite as ill on admission as her son who died after perforation.

CASE 4.—A control. Bridget B., aged 25, admitted on 8th day of disease. Clinically definite. Widal, at first negative, was positive on 13th day for *B. typhosus.* Given 10 c.cm. of normal horse serum on 14th day. Temperature seemed to settle 48 hours later (16th day of disease) but convalescence was slow, and a carditis supervened which persisted for six weeks, the sedimentation-rate of the red cells being still slightly above normal at this late date. Motions were normal 13 days after the injection of horse serum (27th day of disease).

Comment.—This was a mild case of enteric and toxæmia was noted as absent before the patient received horse serum.

CASE 5.—Mrs. C., aged 29, admitted on 8th day of her disease. Clinically a definite enteric, the rose spots being particularly profuse. Widal positive for *B. typhosus,* a blood culture being negative earlier. Given two injections (each 10 c.cm.) of antityphoid serum on 11th and 13th day, after which the disease seemed to abort (Fig. 2), although the motions were not normal until 31st day. On admission toxæmia graded as "+," but within 48 hours after second dose of serum the note was "toxæmia absent."

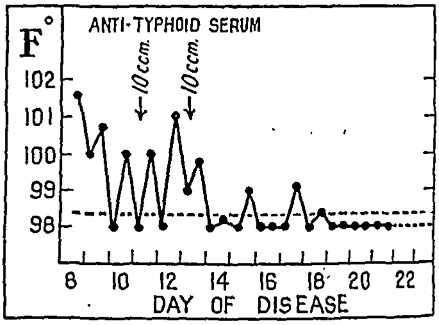

FIG. 2 (Case 5).

CASE 6.—A control. Elizabeth D., aged 23, admitted on 25th day of disease. Clinically an enteric infection. Widal positive for *B. typhosus* in very high titre. Given two doses (each 10 c.cm.) normal horse serum on 26th

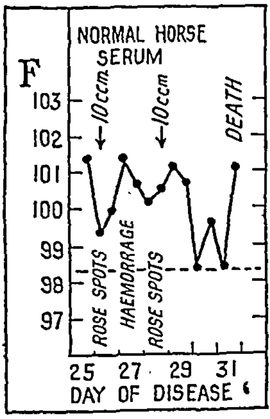

FIG. 3 (Case 6).—Control.

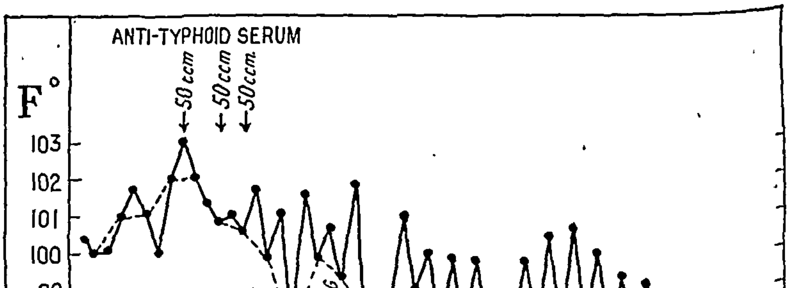

FIG. 4 (Case 7).—S. rash = serum rash. An interrupted line shows the course of the morning temperatures up to the time when they became consistently subnormal.

and 28th day. Hæmorrhage from the bowel occurred on 27th day. This was checked but patient gradually drifted into the typhoid state and died on 31st day (Fig. 3). Toxæmia on admission "++" became "+++" 48 hours after first dose of normal horse serum.

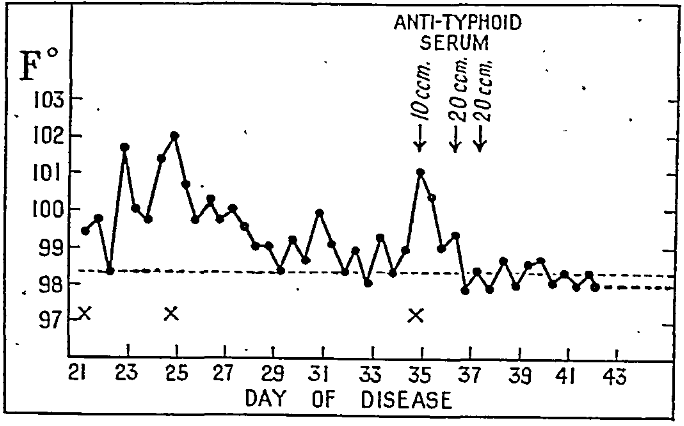

FIG. 5 (Case 9).—× = lumbar puncture.

CASE 7.—Josephine D., aged 21 years, sister of Case 6. Admitted on 5th day of disease. Clinically definite. *B. typhosus* grown from blood during first week. Temperature steadily ingravescent from 100–103° F. for first five days after admission (Fig. 4), pulse-rate varying from 80–90. Toxæmia "+" on admission, "++" on 9th day of illness, when patient received first dose of antityphoid serum (50 c.cm.). Temperature curve immediately became defervescent, the morning temperature being progressively lower on next four days, reaching 98° on 14th day of disease. Same dose (50 c.cm.) serum repeated on 11th and 12th day of illness. With the exception of two pyrexial "mounds" occurring between the 14th and 20th day of disease, the morning temperature remained normal thereafter, the pulse-rate meanwhile fluctuating between 72 and 80. The two mounds in the morning temperature curve (indicated by interrupted line on chart) were definitely related to serum rashes, which—after 150 c.cm. of unconcentrated serum—were to be expected. Motions normal on 23rd day. Toxæmia graded as "+" on day serum treatment started, as "++" on days when second and third doses administered, and as "absent" two days after the last dose given (14th day of disease). The pyrexia occurring during serum rashes was unassociated with anything other than local discomfort. Rose spots continued to appear until the day before the morning temperature finally settled (19th day).

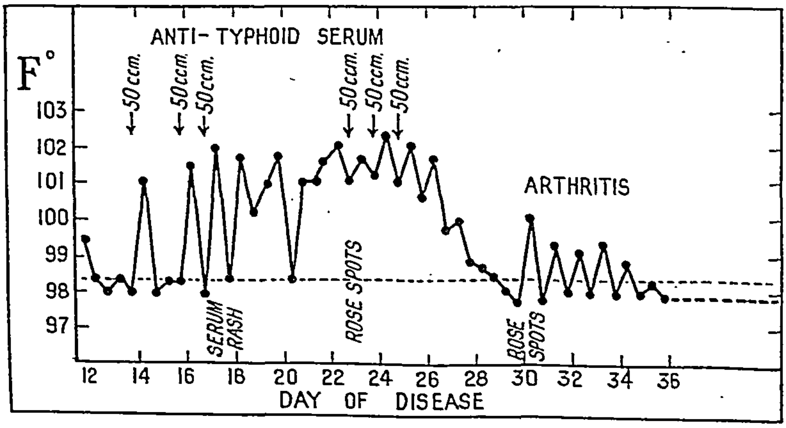

FIG. 6 (Case 10).

Comment.—In this case antityphoid serum seemed to cancel the toxæmia, and to bring the disease to a premature conclusion when the "stage of advance" should normally have occurred.

CASE 8.—A control. Annie D., aged 9 (sister of Cases 6 and 7), admitted on 14th day of disease. Clinically a mild enteric, confirmed by positive blood culture for *B. typhosus* and, later, a Widal. Given three doses (each 50 c.cm.) of normal horse serum. Toxæmia graded as "+" before serum administered, and "absent" on the day on which the last dose was given (25th day). Motions not normal until 41st day of disease.

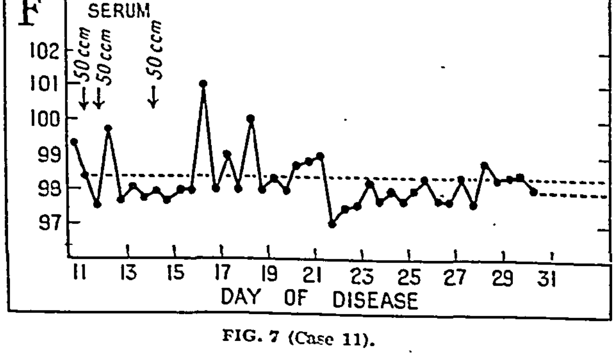

FIG. 7 (Case 11).

Comment.—In this mild case the morning tenperature was normal only once in the third week of the disease, whereas in the case of her sister Josephine (whose ingravescent period had presaged a severe attack) the morning temperature was normal during the same period 4 days out of 7. The toxæmia in the case of the younger child was graded as "+" during this period, whereas with Josephine it was noted as absent. The horse serum in the case of Annie did not seem to accelerate or retard the normal progress of her mild infection towards recovery.

CASE 9.—Mary E., aged 4 years, admitted on 21st day of disease. Child extremely emaciated and presented clinical signs of meningitis which was originally thought to be tuberculous, this suspicion being strengthened when a clear fluid under pressure was obtained by spinal puncture. No tubercle bacilli were isolated from the cerebro-spinal fluid. There were no intestinal symptoms at any time. Spinal puncture repeated 4 days later with similar result —viz., clear fluid under pressure, no tubercle bacilli isolated. Patient now in critical condition, extremely wasted, very irritable, semi-comatose with occasional screaming fits which rendered segregation in a cubicle necessary. A week after the second spinal puncture, the hospital pathologist (Dr. J. H. Pollock) succeeded in isolating an actively motile bacillus from the cerebro-spinal fluid. This "organism was strongly agglutinated by typhoid agglutinating serum, less strongly by Para B serum, and not at all by Para A." The organism gave the typical black colonies on Blair and Wilson's selective medium. A similar motile organism was isolated from an otorrhœa which had developed subsequent to admission. Accordingly, on 35th day of disease, when the temperature was 101° F. and the child apparently moribund, a third spinal puncture was performed and, after clear fluid had been withdrawn, 10 c.cm. of antityphoid serum was administered intrathecally, a dose of 20 c.cm. of the same serum was given intramuscularly on the two succeeding days (Fig. 5). The result was more dramatic than would appear from a study of the temperature charts, although the speedy diminution in pyrexia was itself remarkable. The child became rational, quiet, and proceeded to put on weight rapidly. A week later the case note was "rational now—not irritable." The signs of meningitis cleared, and the patient left hospital mentally and physically normal. Blood submitted for a Widal reaction on the day before serum therapy begun returned weakly positive for *B. typhosus* "*O.*"

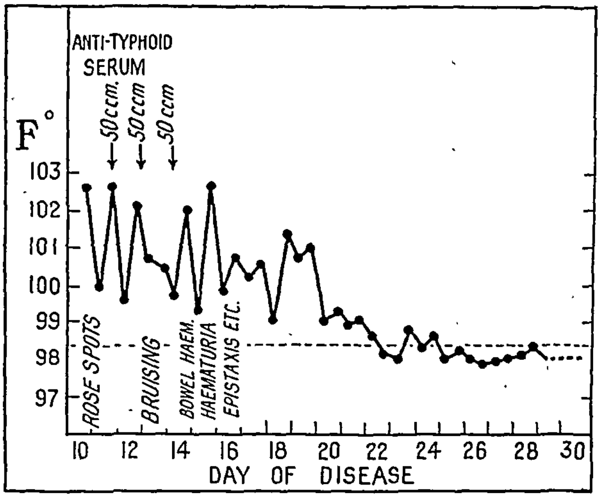

FIG. 8 (Case 12).—Hæm. = hæmorrhage.

Comment.—This case appears to be an instance of primary typhoid meningitis, and a very remarkable amelioration of symptoms and signs, and of pyrexia, with a speedy and complete recovery followed the administration of antityphoid serum.

Case 10.—Nurse F., aged 26, admitted from another hospital on 12th day of disease. Clinically a definite enteric. Blood culture negative for *B. typhosus* on 12th and 21st day but Widal strongly positive for that organism on 14th day. *B. typhosus* later isolated from urine. Received three doses (each 50 c.cm.) of antityphoid serum on 14th, 16th, and 17th day of disease. Temperature did not settle thereafter, a generalised urticarial serum rash appearing on 18th day (Fig. 6). The return of liquid motions, increase in size of spleen, the appearance of rose spots, return of the diazo reaction in the urine, and a rising temperature after the serum rash had faded suggested the onset of a relapse. Serum was repeated on 23rd, 24th, and 25th day of disease, 50 c.cm. being given on each occasion. Two days after the first dose of the second series of injections the temperature will be noted to have taken a downward trend and, apart from a mild attack of arthritis causing local discomfort, convalescence was speedy and complete. This patient never complained after her first serum treatment except about her serum rash and arthritis. The latter was undoubtedly a serum phenomenon, as the patient had in all 300 c.cm. of natural serum, double the maximum dose given to any other case. Motions were normal on 33rd day. Rose spots continued to appear until 30th day.

Toxæmia in this case graded as "++" on admission and "absent" immediately after first series of injections had been completed.

Case 11.—Frank G., aged 54, a bedridden paralytic, admitted on 11th day of disease, much wasted and with extensive bedsores. Clinically a definite enteric, blood culture positive for *B. typhosus*, also Widal and later fæces. On admission toxæmia "++." Given antityphoid serum (3 doses, each 50 c.cm.) on 11th, 12th, and 15th day of disease (Fig. 7). Subsequent toxæmia difficult to assess because of concurrent paralytic and mental condition. Appeared much better from 18th day, temperature remaining settled after 22nd day though motions not normal until 37th day.

Comment.—The clinical impression is that had this man not been given antityphoid serum, he would not, in his lowered state of vitality, have survived his attack of enteric.

Case 12.—Kathleen H., aged 17. Admitted on 10th day of her disease. Clinically a definite enteric. Blood culture and Widal positive for *B. typhosus*. Toxæmia "++" on admission, quickly becoming "+++" on development of hæmorrhages from mucous membranes of nose, mouth, intestine, and bladder. Large areas of subcutaneous hæmorrhage with petechiæ, hæmorrhage into rose spots, and discrete subconjunctival hæmorrhages also occurred. In addition, extravasation took place into the skin of the abdomen, which had been blistered by poulticing before admission. Patient's condition was now very critical and the typhoid state seemed imminent. Antityphoid serum was given in 3 doses of 50 c.cm. on 11th, 12th, and 13th days respectively (Fig. 8). Within 4 days of the last dose her condition showed a remarkable improvement. Toxæmia was definitely less (++), the patient was again rational, hearing less blunted, and all restlessness gone. The urine which had contained a large quantity of blood for several days was clear on 19th day of disease, on which day the toxæmia was noted as absent. Stools were free of blood on 18th day. The temperature was normal on 22nd day, and remained so thereafter. Motions were formed on 26th day.

Comment.—The beneficial effects following serum therapy in this case were the most striking observed in the series of cases under review. Hæmorrhagic typhoid is a very rare disease (E. W. Goodall[2] says he saw only one in his extensive experience, while the late C. B. Ker[3] refers to it as "fortunately most uncommon" and "very fatal").

CONCLUSION

It is, of course, not claimed that any sweeping assertions can be made for the efficacy of this new antityphoid serum on so small a series of observations. This is more especially the case as the controls were, on the whole, not good. It is however possible to say that out of 8 cases receiving antityphoid serum, 7 ceased to cause anxiety within a few days of the last dose, and the only failure was the case receiving a very inadequate single dose who died from a local complication—viz., perforation.

I have to acknowledge the great kindness of Prof. J. W. Bigger who elected to carry out the bacteriological work in connexion with this investigation. I must also express my indebtedness to Dr. F. N. Elcock (senior resident medical officer at Cork-street Hospital) for his careful day-to-day notes on the series of cases here reviewed.

Hospital Treatment for Unemployed.—Lord Derby, as president of the Merseyside Hospitals Committee, has given his support to a new scheme for the provision of voluntary hospital care for unemployed families. This scheme is known as the Friends of the Sick Poor, and a condition of membership is an undertaking to adopt an unemployed family for voluntary hospital care at an annual cost of 10*s.* per family. It is hoped that this scheme will attract support from people who do not come within the penny-in-the-pound fund for Merseyside hospitals.

THE POSTERIOR LOBE OF THE PITUITARY GLAND

ITS RELATIONSHIP TO THE STOMACH AND TO THE BLOOD PICTURE

BY E. C. DODDS, M.V.O., D.Sc., M.D., F.R.C.P. Lond.
COURTAULD PROFESSOR OF BIOCHEMISTRY IN THE UNIVERSITY OF LONDON

G. M. HILLS, B.Sc., Oxon.*

R. L. NOBLE, M.D. Toronto †; AND

P. C. WILLIAMS, B.Sc. Lond.*

(From the Courtauld Institute of Biochemistry, Middlesex Hospital, London)

IT has previously been shown (Dodds, Noble, and Smith [1]; Dodds and Noble [2]) that it is possible to prepare an extract of the posterior lobe of the pituitary gland which when injected subcutaneously into animals will produce an acute hæmorrhagic lesion of the acid-bearing area of the stomach; and the animals usually recover completely in a period of some ten days. The same effects can be produced in rabbits by the oral administration of the extract. These lesions have been described in previous papers in detail. It has been shown that if the contents of the stomach be rendered alkaline prior to injection, it is impossible to obtain the characteristic reaction. The most significant points concerning the gastric lesion are, firstly, its extremely accurate limitation to the area of the stomach in which oxyntic cells are found, and, secondly, the complete absence of lesions in other parts of the alimentary canal. It has also been demonstrated that similar lesions can be produced in all the laboratory animals tested—namely, monkey, cat, rabbit, guinea-pig, rat, and mouse.

The present communication deals with the extension of these investigations, and it will be seen that the extract exerts a profound influence upon the blood picture.

PRODUCTION OF CHRONIC ULCERS

In view of the acute lesions produced by a single injection, it was decided to study the effects of repeated doses of the extract. A typical experiment was as follows: a rabbit was given 40 c.cm. of standard B.P. pituitrin by stomach-tube every 7 days over a period of 8 weeks. During this time the animals appeared to be in good condition and did not exhibit any unusual symptoms after the initial injection. At autopsy a typical punched-out ulcer was found on the greater curvature which had perforated but was healed by omentum. Chronic ulcers have been produced following a single subcutaneous dose of 75 mg. per kg. of the acetone picric acid extract of the posterior lobe of the pituitary. An ulcer has also been found following four subcutaneous injections of 5 c.cm. of standard B.P. pituitary extract, given every other day. These ulcers are always single and situated in the acid-bearing area of the stomach. Their gross appearance is typically that seen in chronic gastric ulcers in man. We believe that this is the first occasion on which chronic gastric ulcers have been produced with any regularity in animals by the injection of an extract of a normal tissue.

EFFECT ON GASTRIC SECRETION

An attempt was made to study the mechanism for the production of the lesion. Since it has been shown that the rendering of the stomach contents alkaline is capable of abolishing the typical lesion, it follows that gastric acidity must in some way be associated with this phenomenon. A technique for studying the reaction of rabbits' stomachs to histamine was worked out. The following is a very brief account of a typical experiment. The rabbits were put on a milk and bran diet for two weeks to allow the stomach contents to become sufficiently liquid to be washed out. Under sodium amytal anæsthesia the pylorus was ligatured, the most dependent portion of the stomach opened, and an external fistula was established. Through this the contents were removed and the stomach was washed out. In the control series of animals the resting juice was collected for half an hour. This was followed by the subcutaneous injection of 0·25 mg. per kg. of histamine. Thirty-minute specimens were collected, and were titrated for free hydrochloric acid and for total acidity. In the experimental group the above technique was followed except that these animals received 2 c.cm. per kg. of standard B.P. pituitrin intravenously, and then after 30 minutes the histamine injection. The control series showed a typical profuse secretion due to the histamine with the free HCl reaching a peak of 80–130 c.cm. of N/10 HCl per 100 c.cm. of juice in 90–120 minutes. In the experimental group we have never found any free HCl secreted, even though large doses of histamine have been repeated at the end of 5 hours. This reaction has also been obtained using the acetone picric acid extract administered intravenously. From these and other experiments it would appear that injection of the extract is capable of causing a temporary inhibition of secretion of hydrochloric acid, in such a way that the stomach will not react to the histamine stimulus for a period of some 6 hours. It is interesting to note at this juncture that other previous workers have called attention to the fact that injection of pituitary extract reduced gastric acidity.[3] [4]

EFFECTS ON BLOOD

It has been shown [5] that very profound changes occur in the blood of animals injected with this extract. Thus, if a rabbit be injected subcutaneously with the preparation, it will be found on the fifth day that a severe anæmia has developed, the blood count being reduced from 6,000,000 down to as low as just over 1,000,000 red cells. The hæmoglobin is also reduced but not proportionately to the same extent. On the fifth or sixth day a reticulocytosis appears which may rise to as high as 50 per cent. There is a marked anisocytosis and a definite macrocytosis. If the animals be killed obvious changes are seen in the spleen, such as hæmorrhagic infarction, and there is evidence of a stimulation of the blood-destroying system. The intestines are full of bile, and it would appear that the anæmia may possibly be ascribed to an increased blood destruction. If left alone the animals will recover completely.

DISCUSSION

It is impossible at the present time to offer any complete explanation of the various phenomena recorded, but the following remarks may assist in an attempt to estimate the significance of these investigations. In the first instance it must be

---

† Working with the Ellen Mickle Fellowship from the University of Toronto.

pointed out that the substance, or substances, responsible for this reaction are contained only in the posterior lobe of the pituitary gland. Exhaustive controls have been made with other tissues of the body, employing not only doses identical to those which prove active in the case of the pituitary, but with doses many times larger. We have, however, been unable to obtain with these any action upon the stomach or blood picture. The following is a list of tissues from which extracts have been prepared: spleen, liver, kidney, testes, muscle, pancreas, suprarenal, brain, stomach, thyroid, and placenta.

As pointed out in previous publications, the factor or factors necessary for the production of a gastric lesion and blood picture are contained in the commercial pituitary extract (B.P.) as well as in the pituitary extract made by the acetone-picric acid process by the method of Dodds and Dickens.[6] It seems at first sight that the quantity of material injected is so great as to make it doubtful whether the phenomena described are really exaggerations of a natural process. It must be borne in mind, however, that the B.P. pituitary extract is standardised for the oxytocic and vasopressive principles in units which bear no relation to the phenomena described. By application of the method of preparation and purification of the vasopressive principle described by Kamm et al.[7] it has been found that the actual weight of an effective dose of the active principle may be reduced to a figure quite compatible with those of other hormones. On the weight basis, therefore, it appears that no theoretical objection could be made to our observations on these grounds.

A full explanation of the connexion between the pituitary gland and the stomach and the blood picture can only be arrived at by a study of the hypophysectomised animal, and this is in active progress at the present time in association with Dr. A. S. Parkes and Mr. I. W. Rowlands.

From the clinical aspect, our observations might possibly provide an explanation for a number of hitherto puzzling phenomena. For example, in Simmonds's disease it is known that there is atrophy of the organs of the reticulo-endothelial system.[8, 9] Again, in certain cases of basophil adenoma of the anterior lobe of the pituitary gland, ulceration of the stomach[10] and also erythræmia have been recorded.[11] In cases of duodenal ulcer polycythæmia has also been observed.[12] The occurrence of acute gastric lesions following operations on the base of the brain has been recorded on several occasions in the publications of Harvey Cushing.[13] From these investigations it seems justifiable to consider the possibility of a hormonal connexion between the posterior lobe of the pituitary gland, the stomach, and the blood picture.

One of us (E. C. D.) is indebted to the Medical Research Council for a grant towards the defrayment of the cost of material for this investigation.

CLINICAL AND LABORATORY NOTES

PARALYTIC ILEUS CURED WITH PROSTIGMIN

By W. E. DAVID, M.C., M.B. Sydney

A REPORT to the Therapeutic Trials Committee of the Medical Research Council published a year ago[1] described the use of prostigmin in a series of cases of abdominal distension following operation. The dose ranged from 1·0 to 4·0 c.cm., but the larger quantity was used on one occasion only and the usual practice was to give 1·0 c.cm., repeated if necessary. None of the patients mentioned in that report seem to have been as gravely ill as the one who is the subject of the present note. The case is interesting not only because almost every known remedy (except acetylcholine) was previously given, but because the dose of prostigmin administered was the large one recommended by Dr. M. B. Walker for the treatment of myasthenia gravis.

A. B., aged 23, was seen on March 30th, 1935, with acute appendicitis. Temp. 101°F; pulse-rate 88. He had had abdominal pain for 48 hours before sending for medical assistance. The operation revealed a gangrenous appendix, which was removed and a drainage-tube inserted. On the following day the tube was changed and the patient was given a turpentine enema, with a very small fæcal result. On April 2nd, at noon, 2 drachms of Cascara Evacuans were given. This was vomited and the dose repeated at 2 P.M. He vomited at 7.30 P.M. and was complaining of abdominal pain and distension. No result from aperient was obtained, so he was given two vegetable laxative tablets at 8 P.M.

He vomited off and on the whole night; the abdomen remained distended and there was no result (either flatus or fæces) from the aperient. Hourly foments were applied to the abdomen and on April 3rd a turpentine enema produced a good fæcal result and he was put on to 1 c.cm. pituitrin, to be followed by 0·5 c.cm. three-hourly. Towards noon his distension had increased and he was unable to pass flatus alone or with the help of a flatus tube. Hiccup began and his distension increased. Nothing abnormal could be felt per rectum. Towards midnight he was given another turpentine enema, which gave a good, formed result, but the abdomen still remained tensely distended and the skin was stretched and shining, and the patient looked drawn, haggard, and altogether extremely ill, although his pulse and temperature did not appear to reflect the severity of his abdominal condition. He was at 12.40 A.M. on April 4th put on to eserine, gr. 1/100 every four hours.

He vomited green bile-stained fluid and hiccupped off and on the whole day. The abdomen at 4.30 P.M. was even more distended and no gurgling could be heard with the stethoscope. A turpentine enema gave a fluid return with streaks of blood-stained mucus, but no flatus was passed. An ox-gall enema was given at 6.20 P.M. with no result, followed at 9.30 P.M. by 20 c.cm. of anti-gas gangrene serum. An hour later the patient was given a spinal anæsthetic (Stovaine) with no result. At midnight he was given an enema of milk and molasses with no result. He was still vomiting and had a very bad night; his temperature on April 5th was 100°, the pulse-rate varying between 90 and 112. He had been having salines subcutaneously and saline and glucose per rectum for the preceding 48 hours, and this was continued throughout the day, and hot fomentations and radiant heat were applied to the abdomen.

---

[1] Carmichael, E. A., Fraser, F. R., McKelvey, D., and Wilkie, D. P. D.: THE LANCET, 1934, i., 942.

At 7.35 P.M. he was given 5 c.cm. of prostigmin subcutaneously. Five minutes after the injection gurgling could be heard in the abdomen and in ten minutes he passed a large action followed by a large quantity of flatus, and his bowels continued to act for 40 minutes. His condition was much improved on the following day, but the abdomen was still somewhat distended despite frequent motions. The effect of 1 c.cm. of prostigmin was tried, but this did not seem to affect the condition in that dosage. The stomach was washed out with saline and half a pint of saline left in. This was repeated twice during the day, and by the evening his vomiting, which had been aggravated by a shortage of chlorides, ceased.

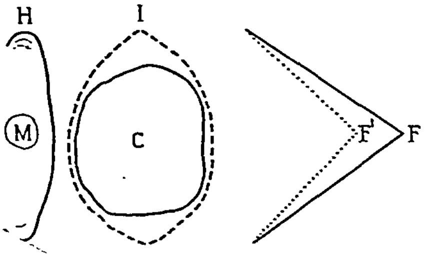
Dr. Walker in the treatment of myasthenia gravis recommends that atropine, gr. 1/100, should be given with the 5 c.cm. of prostigmin, to counteract any slowing of the heart's action and the intestinal peristalsis which ensues. This, of course, was not given in this case, but the pulse was carefully watched and did not vary much as a result of the injection. The point to be stressed is the dosage of prostigmin, and there appears to be little doubt, if one can judge from one apparently hopeless case, that it should be given a trial before other methods as soon as the diagnosis of paralytic ileus has been made.

The cause of paralytic ileus is obscure, but apart from toxæmia there is probably a nervous factor. Anxiety at the thought of an operation may cause over-action of the sympathetic, which is known to have an inhibitory effect on intestinal peristalsis, while a local lesion of the peritoneum or perhaps the gut may cause reflex inhibition of peristalsis. Prostigmin may be presumed to act by antagonising inhibition of both kinds.

CLOSURE OF LARGE POSTAURICULAR FISTULAS AND DEPRESSIONS

BY G. W. DAWSON, F.R.C.S. Irel.
CONSULTING SURGEON TO THE GOLDEN-SQUARE HOSPITAL FOR DISEASES OF THROAT, NOSE, AND EAR, LONDON

SMALL postauricular openings are easily closed. Occasionally, however, one is confronted with cases in which much substance has been lost and an unsightly cavity is left behind the ear with a fistula leading to the additus. The following case illustrates my method of filling such cavities. Mrs. A, aged 30, whilst on holiday in August, 1933, contracted influenza and double acute mastoiditis. An extensive Schwartze operation was performed on each mastoid, and when she was seen by me some as later there was a large depression behind each neasuring 1¼ in. vertically and 1⅛ in. horizontally n some necrosis at lower edge of each cavity ig. 1, C). In one ear there was a fistula leading own to the additus.



1.—The cavity (C) and the incisions and F). H = helix. M = meatus.

An incision (I) was made round the edge of the cavity and the diseased bone was removed. The posterior bony wall of the meatus (M) was lowered and the margins of the bony cavity were well bevelled. A V-shaped incision (F) was then made well behind the cavity, and the entire thickness of the flap was separated from the cranium and displaced forwards. This made it possible to stitch the edges of the incision (I) without any tension, the result being shown in Fig. 2. One side healed by first intention; the other, in which there was a fistula, continued to suppurate through the meatus for a few weeks. The incisions made to form the flap are within the hair margin, heal by first intention, and are invisible. This operation can be combined with a temporal muscle graft.

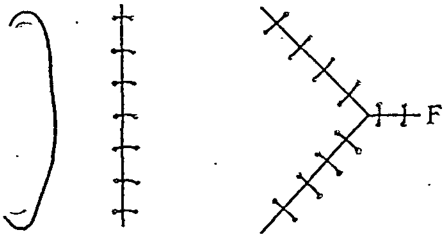


FIG. 2.—The incisions after closure.

POSTURAL HYPOTENSION WITH TACHYCARDIA

BY T. A. HUGHES, M.D. Dub., F.R.C.P. Lond.
LIEUT.-COLONEL, I.M.S.; PHYSICIAN, MAYO HOSPITAL, LAHORE; AND
MOHAMMAD YUSAF, M.D.
CLINICAL ASSISTANT AT THE HOSPITAL

A CASE of postural hypotension has recently been described by Croll and Duthie[1] who give some particulars of previously recorded cases, numbering 18 in all. The chief feature of their case was a fall in the systolic and diastolic pressures, accompanied by giddiness, when the patient changed from the supine to the sitting and from the sitting to the standing position. The fall was associated with a great decrease in the output of water by the kidneys. It was not prevented by abdominal compression, by the application of tourniquets round the limbs, or by the administration of adrenaline, pituitrin, and histamine. The pulse-rate is stated to have showed "a normal response to change in posture—namely, an increase in pulse-rate in the erect position and a decrease in the recumbent." The variation in rate is not given but it was presumably similar to that noticed in normal subjects by Tait McKenzie (whom they quote)—namely, a difference of about seven beats per minute between the lying and the standing positions. Among the other cases referred to by Croll and Duthie is one described by Sanders[2] in which tachycardia and abnormal changes in the electrocardiogram accompanied the fall in blood pressure brought about by change of posture. Indefinite changes in the nervous system were present in three cases described by Bradbury and Eggleston.[3] In Croll and Duthie's patient both knee-jerks were absent and there was a pseudo Argyll Robertson reflex in the left pupil.

Our own patient was a Hind aged 28, a lorry driver, who was admitted ospital, Lahore, on May 26th, 1933, compla ks of palpitation and giddiness associated deal of mental discomfort and difficulty in b loss of appetite, heaviness in the epigas meals, and pain in the lower part of the ch

He had been married for five years and had aged 3½ years and 8 months, both health vegetarian. According to his statement he had been taking opium (amount unknown) for three years but had given it up two months before admission to hospital. There was no history of previous illness other than probable malaria.

History of present illness.—The patient stated that attacks of palpitation and giddiness began about a year before admission and were often accompanied by a sensation of nausea. The attacks ceased when he lay down, but he also found that relief was obtained from walking about. He never fainted and was able to carry on his work. The palpitation and giddiness got no worse during the year, but he became considerably weaker and the pain in the chest rather increased. There was no cough and no loss of sexual power. The temperature occasionally rose to 99° F.

Physical examination.—The patient was 5 ft. 6½ in. in height and of spare build. Nothing abnormal was detected in the heart and lungs by ordinary and X ray examination. The electrocardiogram was normal. The abdomen was somewhat tender and resistant in both iliac fossæ. Skiagraphy showed a spastic colon with stasis. The nervous, genito-urinary, and hæmopoietic systems appeared normal. The teeth and throat were healthy.

The attacks of giddiness, which were related to changes from the horizontal to the erect posture, were associated with a marked increase in the pulse-rate and a less marked fall in the systolic blood pressure. The diastolic pressure was low even in the supine position and altered little with change of posture. Further, the fall in systolic pressure when the patient sat up from the recumbent position was increased very little or not at all on standing, provided he remained sitting for a couple of minutes or so. The pulse-rate, however, was always much more frequent in the standing than in the sitting position. Typical figures were :—

	Recumbent.	Sitting.	Standing.
Blood pressure	110/55	86/55	86/50
Pulse-rate per minute	*70*	*92*	*125*

As in Croll and Duthie's case the blood pressure in the supine position varied from time to time. The readings sometimes went up to 130/70 or thereabouts, the pulse pressure being always relatively high. There was no evidence of aortic incompetence. An injection of 1 c.cm. of adrenaline did not alter the circulatory reaction to changes of posture. The effects of pituitrin, histamine, tourniquets, and abdominal compression were not tried.

A prominent feature of the case was the pronounced tachycardia which seemed to be compensatory for the fall in systolic pressure. This compensation took a little while to adjust itself. When a direct change was made from the supine to the standing position the pulse-rate did not reach a maximum for about two minutes. The increase in heart-rate was brought about through the normal reflex mechanisms. The electrocardiogram showed that a sinus rhythm was maintained in the erect as well as in the horizontal position. With rapid rates the P and R waves coalesced but there was no other change. The low diastolic pressure in the absence of any leak from the arterial system indicated defective vascular tone. The carotid sinus reflex could be easily elicited, a prompt fall in pulse-rate being produced by pressure on either sinus. It is generally stated that compensation for the hydrostatic effects of gravity on the circulation is brought about through the buffer action of the carotid sinus and the aortic nerves. MacWilliam,[4] however, is of opinion that this mechanism acts only in the horizontal position and that compensation in the erect posture is effected through reflexes from some part of the vascular circuit in the lower limbs. Our patient's statement that his "attacks" were relieved by walking about is of interest in this connexion. MacWilliam found that in Croll and Duthie's patient movements of the lower limbs in the erect posture prevented a fall of pressure or even brought about a rise.

The underlying cause of the defect could not be determined. The observed facts indicate that the fault lay chiefly in the effector mechanism of the postural vasomotor reflex. There was no reason to suspect serious derangement of the receptors, nor was there any evidence of disease of the central nervous system. The patient's abdominal symptoms and signs, together with occasional fever, led to a suspicion of abdominal tuberculosis which is fairly common in adult Punjabis. Such a condition might interfere with the action of the splanchnic vasoconstrictor mechanism.

SUMMARY

A case of postural hypotension associated with sinus tachycardia is described in a man aged 28. The cardiovascular system was otherwise normal. It is considered that the tachycardia was compensatory for defective vasomotor control in the erect posture.

MEDICAL SOCIETIES

ROYAL SOCIETY OF MEDICINE

SECTION OF THERAPEUTICS AND PHARMACOLOGY

A MEETING of this section was held on April 30th with Dr. GEORGE GRAHAM in the chair.

Dr. C. A. NEYMANN (Chicago) read a paper on the

Treatment of Disease by Electropyrexia

He traced the history of treatment by fever and observed that some of the earliest pyrexial-producing agents were only in degree more radical than some of the most modern. Fever alone was the important common factor in all methods. The death-rate with malaria treatment of general paralysis ranged between 10 and 20 per cent. and improvement was but slight. Diathermy compared very favourably, showing a 2·5 per cent. death-rate, 34 per cent. improved, and 29 per cent. complete remission. The personal factor accounted for variations in results from different centres; if demented patients were treated with few pyrexial attacks and low temperatures the results would naturally be less good. In private practice Dr. Neymann had had a recovery-rate of 8 per cent. after at least 20 treatments with a pyrexia of 103°–106° F. maintained for 11–14 hours. The death-rate had been negligible—only 1 death in all. The serological changes did not correspond with the clinical benefit, though improvement was noted in some respects. The cerebro-spinal Wassermann reaction was very slow to change, even in patients who had returned to work. Only 2 of 18 patients followed up had failed to continue at work. Diathermy therefore offered a hope of recovery to every early case, but the grandiose type had a better chance than the depressed and slowly dementing. A comparison of three groups of 50 patients treated with sodoku, malaria, and diathermy showed the great superiority of the last method. A single intense bout of fever could not cure when the organisms had adapted themselves to their habitat over years and were heat-resistant from the start.

Tabes was also favourably influenced, and progress could be judged by the arrest of crises and lancinating pains; the benefit was so great and immediate as to be almost unbelievable. Cerebro-spinal fluid and blood changes accompanied the clinical improvement. Several workers had treated the rarer cerebrospinal syphilis; resistant cases were suitable for pyrexial treatment and often responded excellently. The benefit was partly due to destruction of the treponema and partly to the vasodilatation. Syphilitic optic atrophy, treated with intensive pyrexia, up to 107·6° F. for part of the time, had shown some promise: 4 of 7 patients treated had retained the vision they had.

Two male patients with primary chancres had been treated: 1 had recovered and the other had developed secondary symptoms. The urethral temperature was 1° higher than the rectal, and presumably therefore at least 106° was required. One patient so treated had lost his primary lesion, but had developed modified secondaries wherever his skin had been uncovered (and presumably therefore cooled) during treatment. Therefore the more recent patients had been intensively treated in special cabinets, and thermocouples in cisterna magna, rectum, axilla, and under the skin were used to control the temperature throughout the body. External and internal temperatures were kept well above 105° F. Nevertheless, secondaries had appeared, although the chancres healed promptly and were free from organisms. After one treatment the treponema could be seen breaking up and taking on a coccal appearance. Hyperpyrexia therefore could not eradicate the virus, though it influenced and partially arrested the progress of the disease. Work was in progress to find out whether arsenical treatment as an adjuvant was best given during or after the pyrexia.

Four patients with a parkinsonian syndrome had also shown benefit, one of them being enabled to work a typewriter. Multiple sclerosis had been treated in 25 cases. There had been lasting improvement in all mild cases and some improvement in average advanced ones. Four very advanced cases showed no improvement: 1 had died as a result of treatment and 1 soon after it. Sydenham's chorea could be treated by electro-magnetic induction and the results had been astoundingly good. The fever should not be above 104°–105° F. for children. The treatment had also proved beneficial in asthma—22 out of 44 cases showing lasting remission, and others some improvement—and in chronic arthritis. The hypertrophic type of arthritis did not react well to hyperpyrexia, but the chronic infectious type was decidedly improved. Electropyrexia was the treatment of choice in gonorrhœal arthritis. It had been used in many other conditions, but its uncritical application was apt to bring it into disrepute.

Discussion

The CHAIRMAN said that electrical methods of producing fever would remove the undesirable necessity for giving a patient one disease in order to combat another. Although both methods might cause anxiety, yet with electrical treatment the physician knew when the critical times were due. A general paralytic might be exceedingly ill and uncomfortable at noon and perfectly well two hours after the fever was over. He hoped for good results in all cases of asthma

Dr. F. J. NATTRASS, describing the results of short-wave high-frequency currents in the treatment of 15 cases of general paralysis, said that ten or twelve treatments had been considered to be adequate. Dr. Neymann, however, had convinced physicians that this was not a sufficient number. Two of the patients had died as a result of the treatment, and two others afterwards; all had been relatively old and not very suitable cases. From what the lecturer had said, they appeared to have been treated too frequently, treatment having been given on alternate days. Working in a general hospital, he and his colleagues had used amytal and once or twice avertin anæsthesia to mitigate the distress caused by the treatment; morphine had been useless, and hyoscine had caused alarming symptoms, sweat ceasing and pyrexia being difficult to control. In 3 cases of tabes, complete relief from lightning pains had been given by the treatment, and a few cases of gonococcal arthritis had been strikingly benefited.

Dr. NEYMANN, in reply, said that excited and maniacal patients had to be strapped down. Patients with asthma, tabes, and Parkinson's syndrome had to be given relief from the effects of the pyrexia. Hyoscine was very dangerous, but morphine might be used in large doses, starting with gr. ¼, repeated in fifteen minutes if no relief were given. Some cases reacted very well to paraldehyde, but it made the patient smell offensively. Ten drachms might be tolerated without any harm, particularly as the temperature rose and the respiration-rate increased. He deprecated the indiscriminate use of artificial pyrexia in France for practically all diseases. It should, he thought, be kept for diseases to which the body reacted with a small amount of fever: more or less subacute or chronic conditions. It was probably useless in endocrine disorders and malignant disease.

Dr. W. W. PAYNE said that the type of change observed in electrical hyperthermia was complete disappearance of all the phosphate from the urine, and the fall of the inorganic phosphate content of the blood to under 2 mg. per 100 c.cm. as the temperature rose. As it fell, the phosphate rose accordingly. The creatine content followed a slightly different plan, rising and falling with the temperature. The work had all been done with children, who normally excreted creatine in the urine. This creatine would disappear at certain periods between the exposures and would return during pyrexia. The phenomenon was probably due to the breakdown of phosphocreatine in the muscles under the influence of adrenaline. It was difficult to know whether this was a response to the infection or to the fever.

Dr. AGNES SAVILL inquired whether there was any difference in the results of artificial and of natural pyrexia.

Dr. NEYMANN answered that the blood creatine decreased after a series of fever treatments, but increased at the time of each treatment. It increased, like the non-protein nitrogen and the urea nitrogen, as a concentration phenomenon, and finally rested at a lower level. Pyrexia was believed to influence the rapidity of excretion of all waste products. It had been suggested that the treatment might be of some use in chronic interstitial nephritis with nitrogen retention. The lactic acid content of the blood, which was formed from the katabolism of the muscles and of the body, increased under pyrexia. Consequently the hydrochloric acid content of the stomach had at first sight a tendency to increase, but later it decreased on account of the great excretion of salt due to sweating. It would be easy to find out the respective effects of toxæmia and pyrexia if the curves recorded in a bout of toxic fever were reproduced afterwards electrically and physiological observations were made. In conclusion, he said that the particular method used to produce pyrexia was unimportant; it was the man who counted and not the machine. The electro-magnetic induction method heated the inside of the body but not the fat, for it heated tissues in direct proportion to the electrolyte content of the colloids; it therefore did not cause burning.

ROYAL ACADEMY OF MEDICINE IN IRELAND

A JOINT meeting of the sections of medicine and pathology was held on April 5th, with Dr. V. M. SYNGE, president of the section of medicine, in the chair.

Antityphoid Serum

Mr. A. FELIX, D.Sc. (Lister Institute, London), read a paper on experimental and clinical results with a new antityphoid serum. He described experiments from which it was concluded that the efficacy of a therapeutic antityphoid serum would depend on the presence in it of both the Vi and O antibodies. Serum of this type had been prepared from horses at the serum department of the Lister Institute and had given encouraging results in the treatment of cases of typhoid fever in Palestine. These results were described in THE LANCET of April 6th (p. 799).

Dr. C. J. MCSWEENEY reported his experiences with the serum in Dublin. They are set out in detail on p. 1095.

Dr. W. R. O'FARRELL (president of the section of pathology) expressed a hope that Dr. Felix's experiments would throw light on the question of antityphoid vaccination. Referring to the leucopenia constantly present in enteric he suggested that the leucocyte count might be helpful in assessing the immediate effects of the serum.

Prof. J. W. BIGGER said that the Vi antigen described by Dr. Felix was an entirely new conception, and offered great therapeutic possibilities, one of the chief of which was its utilisation in establishing active immunity. The treatment of infections by antibacterial sera had hitherto been very disappointing. The only antibacterial serum which he personally thought was really good was antimeningococcal serum. Here one was dealing with an antiendotoxin. It should however be remembered that the new antityphoid serum was still in the experimental stage, and he thought it should be entrusted only to those prepared to use it in a scientific way, and in a hospital where proper bacteriological facilities existed.

Prof. W. D. O'KELLY asked how a vaccine could be prepared which would contain the Vi antigen, and if the febrile reaction to the vaccine might be neutralised by giving at the same time some serum.

Dr. T. T. O'FARRELL said it was disappointing that Dr. Felix's experiments on mice had not all come out clinically as one would have expected. In the old days many cases of typhoid cured themselves, presumably because the patients produced their own antibodies. In Dr. Felix's experiments there was an enormous number of cases which showed Vi antigen in the serum, and yet in many cases the antibody did not arrive until quite late in the course of the disease. From this one would not think the Vi antibody to be of much use in affecting the progress of a case. Referring to the use of the antiserum, he was rather surprised to hear that in the case of perforation this serum had done good. The danger of perforation was due to the *Bacillus coli* which invaded the peritoneum, and therefore he could not see how antityphoid serum could be useful in these cases.

Prof. LEONARD ABRAHAMSON drew attention to the fact that clinicians had at first used serum only in alternate cases, but after a time had felt obliged to use it in every case.

Dr. G. C. DOCKERAY said that whilst it appeared that in most cases of typhoid Vi antibodies were produced in low titre, in one case described by Dr. Felix the Vi titre was higher on the 77th day than the Vi titre of the therapeutic sera. This suggested the possibility of being able to use convalescent serum derived from patients who did develop high titres.

Dr. A. R. PARSONS pointed out that this was not the first attempt to treat typhoid with serum. In Paris in 1909 cases had been treated with Chantemesse's serum. At first this was reported to give very good results, but very little had been heard of it since. Again, Grasset's serum had been described as very useful, but little was heard of that either. Though the results presented by Dr. Felix and Dr. McSweeney were very good, not enough cases had yet been treated to reach any conclusion statistically.

Dr. R. H. MICKS suggested that Dr. McSweeney should get in touch with county medical officers of health and medical superintendents of country hospitals and ask them to send him their early cases.

Dr. J. FLOOD said that the clinical evidence so far available consisted in the cases Dr. Felix had treated in Palestine and those Dr. McSweeney had treated in Dublin. In his opinion these did not constitute a sufficient number on which to base any definite conclusions. Looking at the temperature charts, the critical period in all of them appeared to be that period at which the patient got the serum. He thought it possible that if Dr. McSweeney had had a series of cases treated with the ordinary antityphoid serum the critical period would have fallen at the same time—namely, the day on which the patient got the serum.

Dr. V. M. SYNGE (president of the section of medicine) agreed with Prof. Bigger that one should not be unduly enthusiastic about this new treatment; the results were very encouraging but the number of cases very small. There was a great deal of typhoid in Ireland, and Dr. McSweeney should have plenty of material to work on.

Dr. FELIX, in replying, said he had been cautious in not drawing any statistical conclusions; to do so would be quite wrong. He was quite aware of the older sera which had been prepared, tested, and abandoned, and was sure that Chantemesse's serum must have been good. It was the only one in whose preparation live organisms had been used. All the sera which were now being produced were produced in a way which destroyed the antibody. It was impossible to compare the in-vitro titres in relation to their protective action. Caution and scepticism were perfectly sound in relation to his serum, which was still in the experimental stage. His purpose in Palestine was to establish whether there was anything to parallel the clear-cut results obtained in animals. He personally would not expect serum to clear up a local complication like a perforation.

Dr. MCSWEENEY said he would be very glad to extend in any way he could the observations in the use of the serum.

of procedure vary. The variations concern the method of making the incision and the conjunctival flap; the method of opening the capsule; the use of preliminary iridectomy; the irrigation of the anterior chamber to get rid of soft lens substance; and the employment of conjunctival sutures. The removal of the lens in its capsule by the "Indian Smith operation" is also briefly described—with its modifications by Knapp, favoured in America, and by A. H. Sinclair of Edinburgh—and also the suction operation of Barraquer. None of them, however, is generally performed by English or American surgeons, whose choice lies rather between the "combined" operation and the "simple" one without iridectomy.

This book gives the generally accepted facts about cataract in an easily readable form. It is well illustrated, well indexed, and well printed.

The Biochemistry of Medicine

Second edition. By A. T. CAMERON, M.A., D.Sc., F.I.C., F.R.S.C., Professor of Biochemistry, Faculty of Medicine, University of Manitoba; Biochemist, Winnipeg General Hospital; and C. R. GILMOUR, M.D., C.M., F.R.C.P. (C.), Professor of Medicine and Clinical Medicine, University of Manitoba; Physician, Winnipeg General Hospital. London: J. and A. Churchill Ltd. 1935. Pp. 518. 21*s*.

Prof. Cameron is well known as a writer of accurate and well-informed works on biochemistry. His association with a clinician, Dr. C. R. Gilmour, has resulted in the addition of a very useful book to the literature of biochemistry as applied to medicine. Much information is here crammed deftly into small space. Our only suggestion concerns the inclusion of detailed descriptions of pieces of work of doubtful value, and in some cases of work which has definitely been disproved, in which obviously the authors themselves have no faith. A good example of this can be seen in the section on the biochemistry of tumours, where several paragraphs are devoted to an entirely discredited serum reaction. This space could have been employed much better by giving a succinct account of, let us say, Warburg's work on the metabolism of malignant and normal tissues, or by a biochemical consideration of the more recent work of Peyton Rous, R. E. Shope, and other investigators. The summary of recent advances in the endocrine glands is a very good one; we would have liked to have seen further details concerning the inter-relationship of the sterol group, the vitamins, and the sex hormones.

The work as a whole is excellent.

A Text-book of Pathology

An Introduction to Medicine. Second edition. By WILLIAM BOYD, M.D., M.R.C.P. Edin., F.R.C.P. Lond., Dipl. Psych., F.R.S.C., Professor of Pathology in the University of Manitoba; Pathologist to the Winnipeg General Hospital. London: Henry Kimpton. 1934. Pp. 1047. 45*s*.

Prof. Boyd's books are notable for their clear exposition and easy style, and through them he has made himself widely known as a teacher of pathology. This second edition of his Text-book of Pathology shows considerable alterations, especially in the arrangement of the section on general pathology. Degenerations are dealt with first, then circulatory disturbances, leading up to inflammation and repair, immunity, bacterial infections, and animal parasites. The chapter on bacterial infections has been rearranged. The section on general pathology concludes with a valuable innovation—a chapter on heredity in disease in which Prof. Boyd discusses in a very brief but illuminating way the theory of inheritance.

The work is still very readable. It covers the subject thoroughly, and the material presented is well chosen and set out rather dogmatically, so that it gives the student clear and unconfused impressions of pathological processes without burdening him with controversial issues. The illustrations are plentiful and well chosen, and the whole work is handsomely produced.

Essays on Chronic and Familial Syphilis

By GRIFFITH EVANS, M.A., D.M., F.R.C.S., Hon. Surgeon, Caernarvonshire and Anglesey Infirmary. Bristol: John Wright and Sons Ltd. 1934. Pp. 91. 7*s*. 6*d*.

THIS small book consists of a series of essays upon an aspect of syphilis which has received little attention—except in France. The author bases his observations upon certain propositions which though not definitely proven are accepted by most syphilologists: (1) that the spirochæte of syphilis has a "dormant, granular" phase, in addition to the spiral form; (2) that untreated syphilis may be transmitted to the third generation; and (3) that even in the absence of a positive Wassermann reaction a diagnosis of syphilis can sometimes be made. He gives a list of the leading symptoms which he has noted in 100 consecutive cases of what he regards as chronic or familial syphilis—the two commonest being abdominal pain and chronic headache which were present together in 41 of the cases. Amongst the physical signs in these same 100 cases, "unequal reacting pupils" were noted in no less than 50, and in the author's experience the most suggestive common signs of latent syphilis are, in addition to inequality of the pupils, smooth, fissured, or fibrotic tongue, persistent tachycardia, and chronic low pyrexia. The presence of these symptoms should, in Mr. Evans's view, lead to the suspicion of syphilis. Acting on these assumptions the author has treated his patients on antisyphilitic lines, generally with marked benefit.

These essays, which were awarded the gold medal of the Hunterian Society, deal with syphilis in relation to nervous dyspepsia, the chronic abdomen, nervous dysphagia, glossitis, and cancer. They provide a thoughtful contribution to our knowledge of syphilis in its less recognised form.

British Journal of Surgery

THE April issue (Vol. XXII., No. 8) includes the following papers:—Progressive Post-operative Gangrene of the Skin, by A. M. Stewart-Wallace (London). The third case to be recorded in England. The gangrene followed drainage of an empyema, and was very extensive, causing death after 32 weeks. The 37 reported cases are reviewed, and treatment by complete excision is recommended.—Adenoma of the Duodenum, by B. R. Sworn and J. Menton (Stafford). The tumour was discovered and removed during an operation of partial gastrectomy for gastric ulcer. It did not apparently add to the symptoms of the case. It proved to be polypoid, and consisted of a hyperplasia of the duodenal glands in a loose stroma.—Measured Dosage in the

Radium Treatment of Carcinoma of the Urinary Bladder, by R. G. Hutchison (Manchester). Open exposure and the use of radon seeds are advocated. A circular distribution of the seed is described, and the calculations required to ensure as uniform as possible a dosage over the field have been reduced to convenient clinical tables.—Interinnomino-abdominal (Hind-quarter) Amputation, by G. Gordon-Taylor and Philip Wiles (London). An account of 5 cases, of which 3 were successful. Particular attention is drawn to the importance of blood transfusion and care in turning the patient during the operation.—The Pathology of Congenital Genu Recurvatum, by D. Stewart Middleton (Edinburgh). A case is described which was successfully treated at the age of 18 months by division of the quadriceps tendon and of its lateral expansions. The condition is considered to be an intrauterine degeneration of muscle-fibres in the quadriceps femoris.—Observations on Fistula-in-Ano in Relation to Perianal Intramuscular Glands, with reports on 3 cases, by Sir Charles Gordon-Watson and Harold Dodd (London). Histological evidence is submitted that infective processes in the perianal glands may be the starting-point of fistulæ and of ischiorectal abscesses.—Schimmelbusch's Disease of the Breast and Dr. A. Lacassagne's Experiments on Mice, by Sir Lenthal Cheatle (London). Lacassagne's observations on young male mice show that injections of œstrin are followed by a series of changes exhibiting a striking similarity in nature and sequence to those described by Cheatle as typical of Schimmelbusch's Disease. In the mouse the changes lead up to adeno-carcinoma.—Osteo-arthritis of the Hip-joint, by T. P. McMurray (Liverpool). The indications for the various forms of treatment are discussed. Manipulation in the early stages, and the Lorenz method of osteotomy are considered to be of most value.—The Pathogenesis of Paget's Disease of the Nipple and Associated Lesions, by Sir Robert Muir (Glasgow). Observations confirming that an intraduct carcinoma of the breast is the underlying cause of Paget's disease. The frequency of adeno-carcinoma is emphasised, as well as its association with ordinary breast carcinoma.—Paraplegia in Pott's Disease, with Special Reference to the Pathology and Ætiology, by R. Weeden Butler (Cambridge).—Pott's Paraplegia: Prognosis and Treatment, by H. J. Seddon (London). These two papers are complementary. In all 186 cases are reviewed: numerous pathological specimens have also been considered. The clinical course of paraplegia occurring at various stages, early and late, in the disease is correlated with the pathological lesions. The value of hyperextension in the prevention and cure of paraplegia, and of the operation of costotransversectomy, are especially stressed.—Skeletal Lipoid Granulomatosis, by John Fraser (Edinburgh). The disease is regarded as a reaction on the part of the reticulo-endothelial tissues to an excess of lipoid in the circulating fluids. Granulomatous tissue is produced in various situations, displacing, compressing, and causing atrophy. Exophthalmos, diabetes insipidus, and calvarial osseous defects are among the clinical results. Treatment is by deep radiotherapy, and cholesterol-free diet.—An Unusual Case of Bone Regeneration after Complete Diaphysectomy on Two Occasions, by J. W. S. Blacklock and W. Rankin. The case was one of acute osteomyelitis of the tibia. The regenerated bone had grown with the general growth of the child, and showed remarkably normal anatomical features.—The Treatment of Spasmodic Dysphagia by Sympathetic Denervation, by Lambert Rogers (London). Operations consisting of complete removal of both superior cervical sympathetic ganglia were carried out in November and December, 1934, and have given complete relief of symptoms.—On Osteo-arthritis in the Dorsal Intervertebral Joints. A study in Morbid Anatomy, by L. R. Shore (Cambridge). Includes an examination of the incidence at various vertebral levels and an interpretation of the findings in relation to mechanical stress.—Polyspondylitis Marginals Osteophytica, by L. R. Shore (Cambridge). The term is used to describe the common type o vertebral disease with "lipping" of the bodies The underlying cause is considered to be loss o normal turgescence of the discs, and strain, ending in ossification, of the deep intervertebral ligaments.—Sympathectomy in the Treatment of Achalasia o the Cardia, by G. C. Knight (Research Laboratorie of Royal College of Surgeons of England). Th ætiology of achalasia and cardiospasm are considered the various types of treatment are reviewed, and th rationale of sympathectomy is explained. An accoun of 3 cases thus treated is given.

Liverpool Medico-Chirurgical Journal

Hugh Owen Thomas's position among moder leaders of British surgery was well brought out i Mr. Frederick Watson's centenary volume dealin with his life and surgical principles and performances The current number of the Liverpool Medico-Chirurgical Journal keeps alive our interest i Thomas, being dedicated to a centenary notice o the man who directly, and indirectly through hi great pupil and nephew Robert Jones, dictated muc of the theory and technique of modern bone surgery Mr. T. P. McMurray, director of orthopædics in the University of Liverpool gives us in the Journal a detailed biography of Thomas made specially acceptable by the appropriate illustrations. His biograph concludes by repeating one of Thomas's own frequent sayings—"I hope I shall not be remembered onl as an inventor of splints, for any mechanical foo can do that; the idea to which they give effect i the important point." Such a narrow impressio of Thomas's work will be removed by the action of the Liverpool Medical Institution, where it is intended to form a Hugh Owen Thomas and Robert Jones library of orthopædic surgery in which it is hoped that every phase of that branch of surgery will be represented. This excellent number of the Journal concludes with an essay on malignant tumours by Mr. Harry Platt, orthopædic surgeon to the Mancheste Royal Infirmary, based upon an address delivered recently at the University of Liverpool, and noticed editorially in THE LANCET last week.

Italian Journal of Allergy

THE first number of *I Quaderni dell' Allergia*, an Italian bi-monthly publication devoted to the subject of allergy, contains a paper by J. Van Niekirk on the altered power of serum from allergic patients to combine with certain pigments. The autho finds the blood-serum from cases of asthma, urticaria, and Quincke's œdema often, but not always, to have a reduced power of combining with pigment as compared with normal sera. This change, however, is not characteristic of the allergic state nor was i possible to establish a parallel between the clinical condition of the patient and the serum reactions. The other papers in this number deal with diagnostic intradermal reactions and climatic allergy. The highly specialised scope of the journal will appeal to research workers in this field. The annual subscription in this country is 80 lire.

CENTENARY OF THE BENGAL MEDICAL COLLEGE

(FROM A CORRESPONDENT)

THE Medical College of Calcutta is this year celebrating its centenary. The record of the first medical school in British India is interestingly told in the Centenary Volume. Before the days of the Medical College the surgeons recruited by the East India Company trained their own Indian assistants. These began as compounders and dressers and had to pass examinations before they were entitled to higher rank and pay. The demand for these men increased, and there was need for a central institution where a more uniform and better system of education could be imparted. The first medical school was sanctioned in 1822 and was opened in October, 1824; it provided for the education of 20 students; instruction was in Sanscrit and Urdu; and the curriculum occupied three years. No dissections were attempted except of lower animals; but the students saw the post-mortems on persons dying in the General Hospital. Pharmacy seems to have been taught with particular care, for Dr. Bretton, the superintendent, in a report to the Medical Board detailed the tuition in the preparation of sulphate of soda, magnesia, muriatic and nitric acids, calomel, hyd. precip. rubrum, and spirits of wine from rice and goor (raw sugar); methods for the purification of benzoin, camphor, and sulphur were also taught. Dr. Bretton reported that the seniors are each made to describe the component parts of the brain, viscera, bowels, and the structure of the eye, and to answer questions. "The zeal and diligence with which the pupils prosecute their studies even in the least attainable part, i.e., anatomy, afford a very cheering prospect of their ultimately becoming one of the most useful class of servants in the service of the British Government in India." This prophecy has been amply fulfilled.

The Calcutta Native Medical Institution, as this school was called, continued till 1835. It had in succession as superintendent Dr. James Jamieson, remembered for his studies of cholera; Dr. Peter Bretton, a versatile author and an early member of a distinguished line of Calcutta ophthalmic surgeons; and Dr. John Tytler, an able Oriental scholar who translated many tracts for the benefit of the students. Tytler sturdily maintained that Indian pupils should be taught in their own vernaculars; but on this point there was much controversy, and the Rev. Dr. Duff, the founder of Scottish Churches College, Calcutta, seems to have advocated English as the medium. The Native Medical Institution had, however, defects, and in January, 1835, on the recommendation of a committee of inquiry, Lord William Bentinck, the Governor General, issued an order in Council decreeing that a new college should be opened to all classes of Indian youths without distinction of creed or caste, and that the instruction should be in English and in strict accordance with "the mode adopted in Europe."

The new Medical College opened in February, 1835, in the premises of the Old Petty Court Jail. The superintendent, Dr. M. J. Bramley, had one assistant, Dr. H. H. Goodeve; 50 students were admitted and the course of study was fixed at four years. The strong prejudice against anatomical dissections had to be overcome. Before the first year was completed Dr. Goodeve had a human body on the lecture table, and in January, 1836, his assistant, Pundit Madhu Sudan Gupta, with four courageous pupils, secretly accompanied Dr. Goodeve to an outhouse of the building, and Gupta began to dissect a body procured for a lecture. A portrait of Madhu Sudan Gupta was presented to the College in 1850 in commemoration of this achievement. It hangs in the anatomical lecture theatre of the present College, and is reproduced in the Centenary Volume. In less than two years practical anatomy had secured its place in the curriculum, and in 1848 Goodeve had a class of 250 "of all nations, colours, religions, and castes co-mingling together as freely and amicably as the more homogeneous frequenters of an European school."

Death exacted a heavy toll in these days; in 1837 Bramley, the first principal, died of fever at the age of 34. He was succeeded by Mr. David Hare, a well-known philanthropist, who was designated secretary of the council and treasurer. The professional staff was increased to five. It included as professor of chemistry Dr. W. B. O'Shaughnessy, who was later knighted, elected F.R.S., and became director-general of posts and telegraphs; as professor of botany, Dr. N. Wallich, M.D., F.R.S.; as professor of surgery, Dr. C. C. Egerton, an original Fellow of the Royal College of Surgeons. The surgeon superintendent of the Calcutta Native Hospital at the time was Dr. J. R. Martin, an original Fellow of the Royal College of Surgeons, later to be knighted, elected F.R.S., and to become the first President of the Medical Board of the India Office. In 1838 a ward of 20 beds was opened, the nucleus of the great hospital which now serves the Medical College. This was not the first hospital in Calcutta, for, as long ago as 1707, the Council of Fort William built a hospital on a "convenient spot close to the Burial Ground." It was north of where St. John's Church now stands and near the mausoleum of Job Charnock. The first Indian hospital was opened in 1793 in Chitpur Road, and three years later was moved to "the open and airy road of Dhurrumtollah" where there were then only three or four houses. It was moved later to Strand Road and is now the Mayo Hospital.

In 1845 the curriculum was remodelled and extended to five years. The following year the Bengal Medical College was the first educational institution in British India to be recognised by the University of London, the Royal College of Surgeons, England, and the Society of Apothecaries, and Dr. Goodeve brought four students to England, all of whom passed the final M.B. London, two proceeding to the M.D. Meanwhile a shorter curriculum with teaching in the vernacular was established to meet the demand for subordinate medical officers in army and civil hospitals. The year 1848 saw the laying of the foundation-stone of the medical college hospital, and four years later it was opened. The Calcutta University was founded in 1857, and with it the Medical College was affiliated. Students henceforth were required to obtain a licence in medicine and surgery or the degree of M.B. or M.D. The first woman student was admitted in 1884, and the first women graduates obtained their degrees in 1889. Nurses seem to have been introduced in 1859; and from 1881 till 1910 the training of the nurses was undertaken by the Clewer sisters from England.

From these early days the history of the Medical College and its hospital has been one of development and expansion. The students now number 754. The College and the associated hospitals cover an area of over 55 acres and adjoining are the daughter institutions, the School of Tropical Medicine and the All-India Institute of Hygiene, the one due to the initiative and enthusiasm of Sir Leonard Rogers and the other to that of Sir John Megaw and the generosity of the Rockefeller Foundation. The College and the group of institutions with which it is surrounded is a worthy memorial to the succession of teachers and administrators supplied by the Indian Medical Service. The end of the first century of its existence coincides with the handing over of the College to the care of those, many of whom are its own sons, and the change is even shown in the new college crest. Their names, it will be hoped, will add to the high reputation won for the College by such predecessors as Jamieson, Martin, Goodeve, O'Shaughnessy, Murchison, Fayrer, Macnamara, D. Cunningham, Lyon, Waddell, Prain, Rogers, and their colleagues.

THE LANCET

LONDON: SATURDAY, MAY 11, 1935

THE POST-GRADUATE SCHOOL

THE opening by the KING on Monday next of the British Postgraduate Medical School at Hammersmith is the biggest event in the history of medical education which most of us will witness. Some may just remember the founding of an undergraduate medical school but nowhere in the Empire is to be found a centre of post-graduate medical education at all comparable with those which are available to the student on the continent and in America. For the newly qualified student, for the general practitioner, for all medical officers employed by the State, the new school will make provision to meet their own particular requirements. In addition the school hopes to be able to provide for more than purely local requirements. Every year many doctors visit London from overseas. There are officers of the naval, military, Indian, and colonial services on leave or study leave, medical missionaries from the outskirts of the Empire, teachers in foreign medical schools, and consultants from our Dominions. Many of these have been coping single-handed with difficult medical problems and large masses of population for whom they are the sole representatives of Western medicine. They have neither had time nor opportunity to discuss their problems with other colleagues. Their knowledge of recent advances is derived solely from the articles they read in the medical journals. They require guidance and advice to make the best use of the experience available. From the more advanced Dominions many students visit London in the hope of doing post-graduate work. They have been educated to regard London as a great centre of medical knowledge and research. Up to the present they have found difficulty in obtaining facilities to follow up their own particular lines of work. Often they have returned discouraged and disheartened or have gone on to continental clinics. For all these overseas visitors the school hopes to provide opportunities for work and means to further their education. The benefit of such work will be felt far beyond the limits of the United Kingdom. Many visitors from overseas complain that much of the instruction available until now has been didactic and impersonal. The school hopes to remedy this and to conduct its teaching not so much by set courses, as by bringing the student and his teachers into personal contact over their cases in the wards. The intimate association thus established will have its effect long after they have left the school.

This is the practical side of the school. There is another side and one which is equally important. It is not merely a gesture that the school forms part of the University of London. It is the intention that the scientific side of medicine should develop pari passu with the practical side. Speak as we may of the science and art of medicine it is only recently that the science of medicine has been recognised as something more than the investigation, by scientific methods, of problems having immediate practical application. One of the main objects of this school will be to study problems in the scientific spirit—to carry on investigation, not because of the immediate practical value of the solution of the problem, but for the advancement of knowledge. With this object in view facilities for research are being provided. Not only are laboratories necessary, and funds to equip them, but fellowships and staffs sufficiently large to relieve the senior members of much of their routine teaching. Encouragement will be given to young graduates desirous of following up lines of research or anxious to take up the academic side of medicine and they will be provided with facilities to work and study in the school. To men having the necessary qualifications and inclination to pursue research, rather than the more profitable branches of practice, the schools will provide the opportunities. Its object will be no less than to provide a training ground for the future teachers of scientific medicine.

The establishment of this school has aroused world-wide interest. Inquiries have been received from all over the world. Visitors have come from Tashkent and Teheran; students are already attending from New Zealand, India, Persia, Spain, and Switzerland. The ambition of all those concerned in its founding and working is that the school shall become a centre of medical education and research of international repute, worthy of the British Empire and commensurate with its size, responsibility, and influence.

THE SURGERY OF CARBUNCLE

DURING the last decade or two a subtle but notable change has come over the general surgical outlook. The anatomical, mechanistic views which so long held sway have gradually given place to a much broader and more rational conception of surgery. The modern surgeon recognises that vital processes are at work and that his gross interventions do no more than direct or divert natural processes into channels that lead to the ascendancy of reparative activity. With this altered mental conception of surgery many changes have taken place, mostly in the direction of restricting operative measures. Surgery is shrinking in its scope. No longer does the diagnosis of tuberculous disease of the lymphatic glands or joints imply operative excision, or the discovery of a movable kidney bring with it an inevitable fixation, or that of severe constipation a short-circuit. In no department of surgery has the modern critical spirit been more pronounced than in the treatment of septic infections. We have seen the delayed treatment of appendicitis, the higher rank and pay. The demand for these men increased, and there was need for a central institution where a more uniform and better system of education could be imparted. The first medical school was sanctioned in 1822 and was opened in October, 1824; it provided for the education of 20 students; instruction was in Sanscrit and Urdu; and the curriculum occupied three years. No dissections were attempted except of lower animals; but the students saw the post-mortems on persons dying in the General Hospital. Pharmacy seems to have been taught with particular care, for Dr. Bretton, the superintendent, in a report to the Medical Board detailed the tuition in the preparation of sulphate of soda, magnesia, muriatic and nitric acids, calomel, hyd. precip. rubrum, and spirits of wine from rice and goor (raw sugar); methods for the purification of benzoin, camphor, and sulphur were also taught. Dr. Bretton reported that the seniors are each made to describe the component parts of the brain, viscera, bowels, and the structure of the eye, and to answer questions. "The zeal and diligence with which the pupils prosecute their studies even in the least attainable part, i.e., anatomy, afford a very cheering prospect of their ultimately becoming one of the most useful class of servants in the service of the British Government in India." This prophecy has been amply fulfilled.

The Calcutta Native Medical Institution, as this school was called, continued till 1835. It had in succession as superintendent Dr. James Jamieson, remembered for his studies of cholera; Dr. Peter Bretton, a versatile author and an early member of a distinguished line of Calcutta ophthalmic surgeons; and Dr. John Tytler, an able Oriental scholar who translated many tracts for the benefit of the students. Tytler sturdily maintained that Indian pupils should be taught in their own vernaculars; but on this point there was much controversy, and the Rev. Dr. Duff, the founder of Scottish Churches College, Calcutta, seems to have advocated English as the medium. The Native Medical Institution had, however, defects, and in January, 1835, on the recommendation of a committee of inquiry, Lord William Bentinck, the Governor General, issued an order in Council decreeing that a new college should be opened to all classes of Indian youths without distinction of creed or caste, and that the instruction should be in English and in strict accordance with "the mode adopted in Europe."

The new Medical College opened in February, 1835, in the premises of the Old Petty Court Jail. The superintendent, Dr. M. J. Bramley, had one assistant, Dr. H. H. Goodeve; 50 students were admitted and the course of study was fixed at four years. The strong prejudice against anatomical dissections had to be overcome. Before the first year was completed Dr. Goodeve had a human body on the lecture table, and in January, 1836, his assistant, Pundit Madhu Sudan Gupta, with four courageous pupils, secretly accompanied Dr. Goodeve to an outhouse of the building, and Gupta began to dissect a body procured for a lecture. A portrait of Madhu Sudan Gupta was presented to the College in 1850 in commemoration of this achievement. It hangs in the anatomical lecture theatre of the present College, and is reproduced in the Centenary Volume. In less than two years practical anatomy had secured its place in the curriculum, and in 1848 Goodeve had a class of 250 "of all nations, colours, religions, and castes co-mingling together as freely and amicably as the more homogeneous frequenters of an European school."

Death exacted a heavy toll in these days; in 1837 Bramley, the first principal, died of fever at the age of 34. He was succeeded by Mr. David Hare, a well-known philanthropist, who was designated secretary of the council and treasurer. The professional staff was increased to five. It included as professor of chemistry Dr. W. B. O'Shaughnessy, who was later knighted, elected F.R.S., and became director-general of posts and telegraphs; as professor of botany, Dr. N. Wallich, M.D., F.R.S.; as professor of surgery, Dr. C. C. Egerton, an original Fellow of the Royal College of Surgeons. The surgeon superintendent of the Calcutta Native Hospital at the time was Dr. J. R. Martin, an original Fellow of the Royal College of Surgeons, later to be knighted, elected F.R.S., and to become the first President of the Medical Board of the India Office. In 1838 a ward of 20 beds was opened, the nucleus of the great hospital which now serves the Medical College. This was not the first hospital in Calcutta, for, as long ago as 1707, the Council of Fort William built a hospital on a "convenient spot close to the Burial Ground." It was north of where St. John's Church now stands and near the mausoleum of Job Charnock. The first Indian hospital was opened in 1793 in Chitpur Road, and three years later was moved to "the open and airy road of Dhurrumtollah" where there were then only three or four houses. It was moved later to Strand Road and is now the Mayo Hospital.

In 1845 the curriculum was remodelled and extended to five years. The following year the Bengal Medical College was the first educational institution in British India to be recognised by the University of London, the Royal College of Surgeons, England, and the Society of Apothecaries, and Dr. Goodeve brought four students to England, all of whom passed the final M.B. London, two proceeding to the M.D. Meanwhile a shorter curriculum with teaching in the vernacular was established to meet the demand for subordinate medical officers in army and civil hospitals. The year 1848 saw the laying of the foundation-stone of the medical college hospital, and four years later it was opened. The Calcutta University was founded in 1857, and with it the Medical College was affiliated. Students henceforth were required to obtain a licence in medicine and surgery or the degree of M.B. or M.D. The first woman student was admitted in 1884, and the first women graduates obtained their degrees in 1889. Nurses seem to have been introduced in 1859; and from 1881 till 1910 the training of the nurses was undertaken by the Clewer sisters from England.

From these early days the history of the Medical College and its hospital has been one of development and expansion. The students now number 754. The College and the associated hospitals cover an area of over 55 acres and adjoining are the daughter institutions, the School of Tropical Medicine and the All-India Institute of Hygiene, the one due to the initiative and enthusiasm of Sir Leonard Rogers and the other to that of Sir John Megaw and the generosity of the Rockefeller Foundation. The College and the group of institutions with which it is surrounded is a worthy memorial to the succession of teachers and administrators supplied by the Indian Medical Service. The end of the first century of its existence coincides with the handing over of the College to the care of those, many of whom are its own sons, and the change is even shown in the new college crest. Their names, it will be hoped, will add to the high reputation won for the College by such predecessors as Jamieson, Martin, Goodeve, O'Shaughnessy, Murchison, Fayrer, Macnamara, D. Cunningham, Lyon, Waddell, Prain, Rogers, and their colleagues.

A DECADE OF PROGRESS IN ANÆSTHETICS

In a retrospect addressed to the section of anæsthetics of the Royal Society of Medicine on Friday last Dr. C. F. **Hadfield** spoke of the work, covering the last decade, of the Anæsthetics Committee jointly set up in 1924 by the Medical Research Council and the section. He recalled its original personnel; this was composed of three anæsthetists, J. **Blomfield**, C. F. **Hadfield**, and **Francis Shipway**, with three other men of science, F. G. **Donnan**, F.R.S., H. H. **Dale**, F.R.S., and M. S. **Pembrey**, F.R.S. Prof. **Pembrey** died in 1934, but the others are still serving and to their number have been added Prof. C. A. **Pannett** and Dr. W. R. **Spurrell**, reader in physiology at Guy's Hospital.

The first important work undertaken by the committee was directed towards the investigation of well-known agents and concerned nitrous oxide gas. Complaints were being made of undesirable symptoms following the inhalation of laughing gas, which had become popular as an anæsthetic during the war, while at that time nitrous oxide was being freely tried by men little versed in its use, at any rate for major surgery. It was suggested in certain quarters that the gas was to blame, and that probably an impure or faulty agent was being provided by the manufacturers. A thorough investigation by the committee of the evidence brought forward, together with scientific as well as clinical testing of the suspected samples, resulted in a complete vindication of the products on the market. The lesson was enforced that when undesirable symptoms arise during anæsthesia it is rarely the drug that should be blamed; most often the fault lies with the administration of it. A further advantage has been gained from the work on nitrous oxide; this compound had not hitherto been included in the British Pharmacopœia, where it now appears complete with tests and standard of purity. That well-known brands of ether and chloroform are as reliable and free from any but negligible amounts of impurity as is nitrous oxide was also proved by the investigations of the committee. Ether, especially, has received a considerable amount of attention since, a few years ago, a suggestion was made by one or two chemists and anæsthetists of standing that pure ether is not itself an effective anæsthetic and that the properties for which it is valued and used are really the properties of its impurities. The committee was able to organise experimental and clinical tests which disproved this theory and established clearly the anæsthetic properties as those of ether itself.. Dr. **Hadfield** showed also how valuable have been the efforts of the committee in obtaining duty-free ethyl alcohol for the manufacture of pure ether, and in establishing a standard preparation in the British Pharmacopœia. The official standard now laid down is very stringent. To make ether of the new B.P. standard from methylated spirit is nearly impossible. The statement that pure ether can be improved by various alterations and additions occurs from time to time; but the B.P. standard for anæsthetic ether is now so strict that it is impossible to believe that any two ethers conforming to it can differ from one another in potency, odour, irritating qualities, or any other significant feature. Any ether good enough to pass the B.P. tests, and to retain the purity thus assured, may be regarded as completely satisfactory for all anæsthetic purposes. Dr. **Hadfield** went on to describe the interesting experiments carried out for the committee by the late Prof. H. B. **Dixon**, F.R.S., on the ignition points of various gases. These led among other lessons to the important practical one that nitrous oxide is not the inert gas that many anæsthetists have supposed it to be, but may be a formidable agent in promoting explosion in certain conditions of temperature and in the association with other gases.

Perhaps even more valuable than its researches into the use of familiar agents has been the work of the committee in connexion with newly introduced anæsthetics. The procedure adopted of enlisting the coöperation of chemical firms has worked admirably in the public interest. It has been made possible for these firms to introduce a new anæsthetic to the profession with the hallmark conferred on it by a favourable report from a research body, which had the opportunity to submit the new product to the clinical and laboratory tests thought desirable. The first anæsthetic dealt with in this manner was Avertin. This had been made, and was already being freely used, in Germany, before the distributors in this country received supplies. Instead of seeking at once to bring these to the notice of the medical profession the manufacturers agreed not to release avertin except to individuals named by the committee. Only when tests had been completed, and a report on their results had appeared in the medical journals, did the manufacturers offer the drug for free sale. This is clearly an excellent way of introducing into practice potent drugs, such as anæsthetics, whose value and safety depend largely on the conditions of their employment. The practitioner may well be misled by glowing accounts arising from the enthusiasm of a pioneer who has blazed a fresh trail in anæsthesia. He may read: "here is an agent which produces perfect muscular relaxation, is pleasant to take, has no undesirable after-effects, and is quite safe." These words represent the terms under which have been introduced many anæsthetics which time and experience have almost completely removed from practice; but many a tragedy may have happened in the interim.

There are anæsthetic drugs whose methods of employment are suitable only for the use of those who are constantly giving anæsthetics; and there are those which the occasional anæsthetist can employ with safety; it is especially in the differentiation between them that the committee can give help. How to discern which agent or method belongs to the former and which to the latter group is by no means easy for the non-specialist, and his difficulties are increased by the speed with which his patients delayed opening of empyema, the limited operations for osteomyelitis and cellulitis, the non-operative management of carbuncle, and the closed treatment of septic compound fractures. In a paper published in THE LANCET on April 13th, Dr. J. T. INGRAM, dealing with certain septic infections of the skin, goes even further. Writing of whitlows he declares dry heat to be always better than wet, macerating heat; he holds that septic perionychia should never be treated surgically, and he makes an earnest plea for the conservative treatment of boils and carbuncles, believing firmly that these lesions should never be subjected to operative trauma. Similarly Mr. P. H. MITCHINER, from the study of statistics of cases treated at St. Thomas's Hospital, has come to the conclusion, in common with other English and continental surgeons, that operating upon a facial carbuncle raises the mortality-rate.[1]

It is a maxim of surgical therapy, dating from antiquity and based upon countless observations of generations of men, that evacuation of pus is a definitely curative act. Thousands of experiments have proved beyond any doubt the essential truth of this tenet. Hence the assertion that a boil of any size should be treated by an occlusive dressing is not likely to be accepted by surgeons unless it is backed by overwhelming evidence. At the same time the critical attention given to the subject is useful if it does no more than emphasise the undesirability of early surgical intervention in most septic infections. One of the beneficent results of the closer study of these diseases and the reconsideration of surgical practice has been the greater recognition of the predominating rôle of the tissues. Whether it be a boil, a carbuncle, or an acute osteomyelitis, limitation of the disease must finally be brought about by a combination of general and local body reactions. Which of these is the more important it is impossible with our present knowledge to say, but it is an interesting and significant observation that cellulitis may clear up in one region of the body while it may be progressing in another even to a fatal termination. What the insistence on abstention from surgical incision does emphasise is that nothing must be done which might in any way disturb the natural indispensable local reactions of the tissue cells. It is a perfect truth to say that, under certain circumstances, the incision of a boil, a carbuncle, a cellulitis, or a whitlow, is a meddlesome, unnecessary, harmful, and even death-dealing action, but it would be robbing surgery of one of its most powerful therapeutic weapons to forbid such incisions under all conditions. Indeed most surgeons would claim that their personal experience shows that after a certain local response of tissue cells has occurred around a carbuncle a judicious incision not only gives great subjective relief but does seem to hasten the healing process. Scraping, because of the traumatisation involved, always appears to be harmful, but it is difficult not to believe that the simple incision which relieves tension and lessens pain does not also have a directly curative effect by allowing fresh immune plasma access to the formerly tightly distended tissue spaces. It is the selection of the correct time for such incisions that is of such great importance and in this lies the art of surgery, for as yet we have no rules, no measurable phenomena or reactions which can tell us just when the necessary tissue response has taken place.

The decision needs particular care and thought when it is a question of operating on facial boils and carbuncles, especially those of the upper lip and beside the nose; for in such cases dissemination by the veins to the cavernous sinus is not uncommon. Anatomical arrangements no doubt play the major part in this terrible result. Unlike other regions of the body, the face has no deep fascia to limit the infection to the subcutaneous tissue, and the infective process accordingly has direct access to muscles, with their abundant venous channels, and to the nearby facial trunk. Its spread is probably helped also by the involuntary movement of the muscles of facial expression which cannot be wholly checked. In Mr. MITCHINER's figures from St. Thomas's Hospital 2 out of 10 patients with facial carbuncle in whom an incision was made died, whilst of 73 treated conservatively only 5 succumbed. It is true that this series of cases is not large but there are other series from different clinics which point the same way, and though the evidence for the policy of conservatism for facial carbuncle can certainly not be regarded as conclusive, it clearly needs careful consideration. Of other methods of treating carbuncles excision must receive attention in view of the experience at St. Thomas's Hospital. If excision is done, it must be wide to be effective and the better results of excision (over incision) may have been due to the fact that only the smaller lesions were excised. Certainly most surgeons who have practised both measures would agree that healing is much delayed after excision. Whether a carbuncle is treated conservatively or by incision, it is remarkable how much of the epithelium seems to escape destruction by the septic process and survives to form points of regeneration; but all this advantage is lost when it is excised. Incision by the diathermy knife also has its advocates, though it is difficult to see how this can be an improvement on knife incision and indeed how it can give any relief at all. The object of an incision is to provide an exit for pathological humours and to give free flow to immune plasma—both of which objects are frustrated by the diathermy knife, which seals as it cuts. Indeed it is curious how very little is really known of the effect of different methods of treatment on so common a malady. The collection of a mass of controlled data and their correlation are urgently required, and it is essential that we should know how the results of the most satisfactory operative technique compare with those of the short-wave and X ray therapy now widely recommended. Surgical research could hardly be devoted to more useful ends.

---

[1] THE LANCET, March 2nd, 1935, p. 507.

points out, there is experimental evidence that an inappropriate antistreptococcal serum or even normal horse-serum may have a deleterious action on the course of the disease. This would not apply, of course, to normal *human* serum which has been used by some clinicians to supply a deficiency of complement in the treatment of septicæmia.

Whether or not with increasing knowledge of the hæmolytic streptococci we shall be in a position to devise sera to combat those infections not primarily toxigenic only the future will disclose. The work of F. T. CADHAM, which was referred to at length in a recent issue of this journal, is an attempt to provide a solution to this problem. In the meantime however Dr. COLEBROOK'S plea for the abandonment of the indiscriminate use of streptococcal antisera in puerperal and surgical sepsis should receive serious attention. It is recognised, though not always remembered, that even under experimental conditions the various sera prepared against bacteria or their toxins often have but little curative action.

ANNOTATIONS

THE JUBILEE FESTIVAL

THE Jubilee ceremonial was a complete success; its object was attained. The King and Queen received an acclaim of personal loyalty and affection such as few, if any, reigning sovereigns have ever experienced; a precocious summer day lent a splendour to proceedings which, despite the gorgeousness of trappings and accessories, were of a simple nature; and organisation of a thorough kind averted the dangers inherent in the massing of crowds. The total size of the crowds which, from stands, balconies, and roofs, from trees, lamp-posts, and walls, from pavement, windowsill, and gutter, saw the Royal procession pass, may be capable of near estimation by experts on such matters; but whatever it was, it was tremendous. And the casualty roll, in proportion to the numbers involved, appears to have been negligible. The whole parade of the St John's Ambulance Brigade was in charge of Captain W. Goodley, M.C., the commissioner of the London Brigade. There were on duty 3000 men and 1000 women. Fifty-seven doctors were also posted along the line of route. There were 71 stations and 25 ambulances. Dr. Ernest McIntyre was in charge of the ambulance arrangements inside the cathedral. In all 7500 cases were treated along the route. In the evening members of the brigade, who had been on duty since 8 A.M., were stationed at the floodlighting and bonfires, and many of them remained on duty until 2 and 3 A.M. The total number of casualties treated during the evening has not yet been received. Members of the brigade will be on duty every evening this week from 8 P.M., and there will be 18 stations in the neighbourhood of the floodlighting. The speed and efficiency of the work rendered by the brigade during the procession were objects of general admiration and in particular impressed the numerous foreign visitors unofficially present.

ROYAL ACADEMY EXHIBITION

THE 167th Exhibition of the Royal Academy of Arts was opened on Friday last, and may be considered fairly to represent modern tendencies on the part of the majority of the public, which tendencies must be responded to by the majority of artists. What may seem very individual tastes are also met at this exhibition by very individual exponents. Among the oil paintings the resolution to be modern and to be different is certainly strained to the point of making some of the representations appear distorted to the amateur or unaccustomed eye, but a good proportion of them meet a desire for beauty, and that is what the majority of people hope to satisfy when looking at pictures. The circumstances of social life to-day have led the class that is best able to buy pictures to live in smaller rooms, and no doubt the exhibitions in the Academy galleries have been rendered more pleasing by the absence of the overcrowding formerly brought about through the size of many of the exhibits. Immense landscapes are few this year, and detailed stories in colour are fewer. With the disappearance of the anecdotal picture all scenes of medical life have gone from the walls, and our profession only enters the exhibition through the medium of the portraits of certain of its members. Among these may be noted a sympathetic and workmanlike portrait of Sir George Newman by Miss M. L. Williams; the presentation portrait of the veteran Sir James Crichton Browne by Mr. Oswald Birley; and an excellent portrait of Dr. G. F. Still by Mr. Gerald Kelly, R.A., which is destined to be hung in King's College Hospital, London. A picture from the brush of Mr. F. W. Elmlie, A.R.A., will take the eye as a skilful piece of work; this is a presentation portrait of Lieut.-Colonel Samman in character as Master of the Society of Apothecaries of London. The portrait of Prof. Cunningham M'Lennan, F.R.S., by Mr. Augustus John, R.A., may fairly be included in a medical category, as Prof. M'Lennan, a distinguished physicist and physiologist, shared the Nobel prize in medicine in 1923.

ARE ANTIBODIES PROTEINS?

THE nature of antibodies is not of theoretical interest only, for if they were shown not to be proteins there would be a hope of making active protein-free preparations from antisera, and thereby avoiding the risks of serum sickness and anaphylaxis. Almost all investigators who have attempted to prepare antibodies free from protein have reported failures, however, and in most of the few instances in which success has been recorded, the antibody solutions have been so weak that their protein content would be below the range of the not very delicate tests used. One of the claims to which this explanation did not apply was that of M. Frankel and L. Olitzki, but Rosenheim [1] has lately reported a complete failure to repeat their experiments. Moreover, the less direct methods of investigation all point to the protein nature of antibodies. For example, in reactions in which a precipitate is formed, the precipitate contains the antigen together with protein from the antiserum. It might be supposed that the protein thus precipitated from the antiserum was either the actual antibody or non-specific protein adsorbed on the antigen-antibody complex. Recent work has shown that the amount of protein precipitable from a given amount of an antiserum is constant. Heidelberger and Kendall [2] have confirmed gain, from the daily press, a superficial acquaintance with the properties of the latest innovations in anæsthetics. When the patient demands the wonderful drug which "simply sends you straight off—like that!" the doctor must ascertain first and foremost whether he dare try it himself or whether it is a drug that should only be given by an expert, quite apart from its suitability in any particular case. Most of the effective basal anæsthetics, for example, can hardly be used to the best advantage except by those who are constantly engaged with anæsthetics; yet almost the latest barbiturate, Evipan, has such value for the general practitioner that it would be well worth his while to master the technique of its administration, and make himself familiar with its risks, indications, and contra-indications for its use. Cyclopropane, on the other hand, has been shown by the work of the committee to be a potent anæsthetic with many valuable qualities, but essentially one which should be used only by experienced anæsthetists. Acetylene, Butylene, Cyclohexine, Dimethyl ether, Ethylene, Propylene, and Vinethene are among the many other agents which have been investigated by the committee, whose activities have contributed directly or indirectly to the inclusion of several gases in the latest edition of the British Pharmacopœia, notably nitrous oxide, carbon dioxide, ethylene, and oxygen. The work done by the committee, in fact, gives a good illustration of the immense value of close coöperation between those engaged in a solely practical and clinical branch of medicine and the purely scientific worker.

ANTISTREPTOCOCCAL SERA IN PUERPERAL FEVER

THAT these sera possess protective value, often of a very high order, can be readily demonstrated, but quite commonly, a serum found to be potent when used prophylactically, will prove of little value in experiments designed to test its *curative* properties. Bearing this in mind it will be realised that at times in the serum therapy of human disease, we expect from these sera something which is beyond their power to achieve. Our astonishment should be not that they sometimes fail us, but that they so often seem to have therapeutic value. Prior to the demonstration that the hæmolytic streptococcus produced a soluble toxin, antisera prepared against these micro-organisms were of the antibacterial type, and it has to be admitted that the sera used in the treatment of streptococcal infections in man has been, at the best, disappointing. But with the production of potent antitoxic streptococcal sera, of which, of course, scarlatinal antitoxin is the outstanding example, and the demonstration that all toxigenic strains of *S. hæmolyticus* produced the same toxin, it was hoped that here, at last, was a type of serum which would be of real service in clinical medicine. Has this hope been realised? As far as the use of antitoxin in the treatment of scarlet fever is concerned the answer would appear to be in the affirmative. It has to be remembered, however, that in scarlet fever one is dealing with a type of hæmolytic streptococcus which, though highly toxigenic, is not very invasive, and it is precisely in these circumstances that one would expect such a serum to be effective. Can such a serum influence favourably the course of infection due to a hæmolytic streptococcus of invasive tendency? The answer to this question is by no means clear. Some observers speak enthusiastically of their experience with streptococcus antitoxin, others doubt its efficacy, some think even that the serum may at times be harmful.

In a paper appearing elsewhere in this issue Dr. LEONARD COLEBROOK discusses the use of antistreptococcal serum in the treatment of puerperal fever. He has collected 69 cases which had received serum prior to admission to Queen Charlotte's Hospital—antistreptococcal sera have not been used in the isolation block in this hospital—and has contrasted the results obtained in this group with cases not treated with serum. He admits that he has not been able to obtain complete details of the serum treatment in every case, but the information obtained from the medical men who treated these patients before sending them to Queen Charlotte's shows that only 30 out of the 69 were known to have received concentrated scarlatinal antitoxin; the others had "antistreptococcal serum." The amount of serum administered varied from 10 to 140 c.cm., mostly given by the intramuscular route. There was no evidence that the cases receiving serum differed materially in other respects from the unselected admissions not treated with serum. The percentage case-mortality in these two groups is somewhat unexpected. In the first group—those receiving serum—there were 21 deaths giving a case-mortality of about 30 per cent., whereas in the group of 932 cases which received no serum 108 died, a case-mortality of about 11 per cent. It should be added that bacteriological examination revealed the hæmolytic streptococcus as the infecting agent in 40 and 346 of the two groups respectively; there were 29 patients in the serum-treated group in which no one could expect the serum to be beneficial. But if comparison is limited to those in the two groups known to be infected with the streptococcus, the case-mortality still works out unfavourably for serum, 45 and 22 per cent. respectively. In addition to these figures of his own, Dr. COLEBROOK cites the observations of BENSON and RANKIN on 114 cases of puerperal infection from whose blood hæmolytic streptococci were grown in every case. Half of this group was treated with serum (37 with scarlatinal antitoxin and 20 with puerperal antistreptococcus serum); the other half served as controls. The mortality-rate was 75 per cent. in the serum-treated group and 72 per cent. in the controls. All will agree with Dr. COLEBROOK'S conclusion that such evidence does not support the use of antiserum in the treatment of hæmolytic streptococcal infections in man, at any rate in infections of the invasive type. He naturally hesitates to ascribe to the serum the higher mortality in his serum-treated group, but, as he points out, there is experimental evidence that an inappropriate antistreptococcal serum or even normal horse-serum may have a deleterious action on the course of the disease. This would not apply, of course, to normal *human* serum which has been used by some clinicians to supply a deficiency of complement in the treatment of septicæmia.

Whether or not with increasing knowledge of the hæmolytic streptococci we shall be in a position to devise sera to combat those infections not primarily toxigenic only the future will disclose. The work of F. T. CADHAM, which was referred to at length in a recent issue of this journal, is an attempt to provide a solution to this problem. In the meantime however Dr. COLEBROOK'S plea for the abandonment of the indiscriminate use of streptococcal antisera in puerperal and surgical sepsis should receive serious attention. It is recognised, though not always remembered, that even under experimental conditions the various sera prepared against bacteria or their toxins often have but little curative action.

ANNOTATIONS

THE JUBILEE FESTIVAL

THE Jubilee ceremonial was a complete success; its object was attained. The King and Queen received an acclaim of personal loyalty and affection such as few, if any, reigning sovereigns have ever experienced; a precocious summer day lent a splendour to proceedings which, despite the gorgeousness of trappings and accessories, were of a simple nature; and organisation of a thorough kind averted the dangers inherent in the massing of crowds. The total size of the crowds which, from stands, balconies, and roofs, from trees, lamp-posts, and walls, from pavement, windowsill, and gutter, saw the Royal procession pass, may be capable of near estimation by experts on such matters; but whatever it was, it was tremendous. And the casualty roll, in proportion to the numbers involved, appears to have been negligible. The whole parade of the St John's Ambulance Brigade was in charge of Captain W. Goodley, M.C., the commissioner of the London Brigade. There were on duty 3000 men and 1000 women. Fifty-seven doctors were also posted along the line of route. There were 71 stations and 25 ambulances. Dr. Ernest McIntyre was in charge of the ambulance arrangements inside the cathedral. In all 7500 cases were treated along the route. In the evening members of the brigade, who had been on duty since 8 A.M., were stationed at the floodlighting and bonfires, and many of them remained on duty until 2 and 3 A.M. The total number of casualties treated during the evening has not yet been received. Members of the brigade will be on duty every evening this week from 8 P.M., and there will be 18 stations in the neighbourhood of the floodlighting. The speed and efficiency of the work rendered by the brigade during the procession were objects of general admiration and in particular impressed the numerous foreign visitors unofficially present.

ROYAL ACADEMY EXHIBITION

THE 167th Exhibition of the Royal Academy of Arts was opened on Friday last, and may be considered fairly to represent modern tendencies on the part of the majority of the public, which tendencies must be responded to by the majority of artists. What may seem very individual tastes are also met at this exhibition by very individual exponents. Among the oil paintings the resolution to be modern and to be different is certainly strained to the point of making some of the representations appear distorted to the amateur or unaccustomed eye, but a good proportion of them meet a desire for beauty, and that is what the majority of people hope to satisfy when looking at pictures. The circumstances of social life to-day have led the class that is best able to buy pictures to live in smaller rooms, and no doubt the exhibitions in the Academy galleries have been rendered more pleasing by the absence of the overcrowding formerly brought about through the size of many of the exhibits. Immense landscapes are few this year, and detailed stories in colour are fewer. With the disappearance of the anecdotal picture all scenes of medical life have gone from the walls, and our profession only enters the exhibition through the medium of the portraits of certain of its members. Among these may be noted a sympathetic and workmanlike portrait of Sir George Newman by Miss M. L. Williams; the presentation portrait of the veteran Sir James Crichton Browne by Mr. Oswald Birley; and an excellent portrait of Dr. G. F. Still by Mr. Gerald Kelly, R.A., which is destined to be hung in King's College Hospital, London. A picture from the brush of Mr. F. W. Elmlie, A.R.A., will take the eye as a skilful piece of work; this is a presentation portrait of Lieut-Colonel Samman in character as Master of the Society of Apothecaries of London. The portrait of Prof. Cunningham M'Lennan, F.R.S., by Mr. Augustus John, R.A., may fairly be included in a medical category, as Prof. M'Lennan, a distinguished physicist and physiologist, shared the Nobel prize in medicine in 1923.

ARE ANTIBODIES PROTEINS?

THE nature of antibodies is not of theoretical interest only, for if they were shown not to be proteins there would be a hope of making active protein-free preparations from antisera, and thereby avoiding the risks of serum sickness and anaphylaxis. Almost all investigators who have attempted to prepare antibodies free from protein have reported failures, however, and in most of the few instances in which success has been recorded, the antibody solutions have been so weak that their protein content would be below the range of the not very delicate tests used. One of the claims to which this explanation did not apply was that of M. Frankel and L. Olitzki, but Rosenheim [1] has lately reported a complete failure to repeat their experiments. Moreover, the less direct methods of investigation all point to the protein nature of antibodies. For example, in reactions in which a precipitate is formed, the precipitate contains the antigen together with protein from the antiserum. It might be supposed that the protein thus precipitated from the antiserum was either the actual antibody or non-specific protein adsorbed on the antigen-antibody complex. Recent work has shown that the amount of protein precipitable from a given amount of an antiserum is constant. Heidelberger and Kendall [2] have confirmed gain, from the daily press, a superficial acquaintance with the properties of the latest innovations in anæsthetics. When the patient demands the wonderful drug which "simply sends you straight off—like that!" the doctor must ascertain first and foremost whether he dare try it himself or whether it is a drug that should only be given by an expert, quite apart from its suitability in any particular case. Most of the effective basal anæsthetics, for example, can hardly be used to the best advantage except by those who are constantly engaged with anæsthetics; yet almost the latest barbiturate, Evipan, has such value for the general practitioner that it would be well worth his while to master the technique of its administration, and make himself familiar with its risks, indications, and contra-indications for its use. Cyclopropane, on the other hand, has been shown by the work of the committee to be a potent anæsthetic with many valuable qualities, but essentially one which should be used only by experienced anæsthetists. Acetylene, Butylene, Cyclohexine, Dimethyl ether, Ethylene, Propylene, and Vinethene are among the many other agents which have been investigated by the committee, whose activities have contributed directly or indirectly to the inclusion of several gases in the latest edition of the British Pharmacopœia, notably nitrous oxide, carbon dioxide, ethylene, and oxygen. The work done by the committee, in fact, gives a good illustration of the immense value of close coöperation between those engaged in a solely practical and clinical branch of medicine and the purely scientific worker.

ANTISTREPTOCOCCAL SERA IN PUERPERAL FEVER

That these sera possess protective value, often of a very high order, can be readily demonstrated, but quite commonly, a serum found to be potent when used prophylactically, will prove of little value in experiments designed to test its curative properties. Bearing this in mind it will be realised that at times in the serum therapy of human disease, we expect from these sera something which is beyond their power to achieve. Our astonishment should be not that they sometimes fail us, but that they so often seem to have therapeutic value. Prior to the demonstration that the hæmolytic streptococcus produced a soluble toxin, antisera prepared against these micro-organisms were of the antibacterial type, and it has to be admitted that the sera used in the treatment of streptococcal infections in man has been, at the best, disappointing. But with the production of potent antitoxic streptococcal sera, of which, of course, scarlatinal antitoxin is the outstanding example, and the demonstration that all toxigenic strains of *S. hæmolyticus* produced the same toxin, it was hoped that here, at last, was a type of serum which would be of real service in clinical medicine. Has this hope been realised? As far as the use of antitoxin in the treatment of scarlet fever is concerned the answer would appear to be in the affirmative. It has to be remembered, however, that in scarlet fever one is dealing with a type of hæmolytic streptococcus which, though highly toxigenic, is not very invasive, and it is precisely in these circumstances that one would expect such a serum to be effective. Can such a serum influence favourably the course of infection due to a hæmolytic streptococcus of invasive tendency? The answer to this question is by no means clear. Some observers speak enthusiastically of their experience with streptococcus antitoxin, others doubt its efficacy, some think even that the serum may at times be harmful.

In a paper appearing elsewhere in this issue Dr. Leonard Colebrook discusses the use of antistreptococcal serum in the treatment of puerperal fever. He has collected 69 cases which had received serum prior to admission to Queen Charlotte's Hospital—antistreptococcal sera have not been used in the isolation block in this hospital—and has contrasted the results obtained in this group with cases not treated with serum. He admits that he has not been able to obtain complete details of the serum treatment in every case, but the information obtained from the medical men who treated these patients before sending them to Queen Charlotte's shows that only 30 out of the 69 were known to have received concentrated scarlatinal antitoxin; the others had "antistreptococcal serum." The amount of serum administered varied from 10 to 140 c.cm., mostly given by the intramuscular route. There was no evidence that the cases receiving serum differed materially in other respects from the unselected admissions not treated with serum. The percentage case-mortality in these two groups is somewhat unexpected. In the first group—those receiving serum—there were 21 deaths giving a case-mortality of about 30 per cent., whereas in the group of 932 cases which received no serum 108 died, a case-mortality of about 11 per cent. It should be added that bacteriological examination revealed the hæmolytic streptococcus as the infecting agent in 40 and 346 of the two groups respectively; there were 29 patients in the serum-treated group in which no one could expect the serum to be beneficial. But if comparison is limited to those in the two groups known to be infected with the streptococcus, the case-mortality still works out unfavourably for serum, 45 and 22 per cent. respectively. In addition to these figures of his own, Dr. Colebrook cites the observations of Benson and Rankin on 114 cases of puerperal infection from whose blood hæmolytic streptococci were grown in every case. Half of this group was treated with serum (37 with scarlatinal antitoxin and 20 with puerperal antistreptococcus serum); the other half served as controls. The mortality-rate was 75 per cent. in the serum-treated group and 72 per cent. in the controls. All will agree with Dr. Colebrook's conclusion that such evidence does not support the use of antiserum in the treatment of hæmolytic streptococcal infections in man, at any rate in infections of the invasive type. He naturally hesitates to ascribe to the serum the higher mortality in his serum-treated group, but, as he the condition. Later in the disease plasma cells and lymphocytes largely replace the previously existing stem cells.

Dr Adams supplies a useful appendix containing a list of preparations known to contain amidopyrin, which in view of the evidence he marshals must be considered a dangerous drug. Some of the listed preparations are recognised hypnotics; others are advertised pick-me-ups likely to be bought without a doctor's prescription.

POUL EDVARD POULSSON

THE death of Prof. Poulsson on March 19th removes an outstanding figure from the world of pharmacology. His text-book, originally published in Norwegian, has been translated into many languages and has enjoyed a popularity remarkable for a translated work. In many, if not most subjects, the Norwegian medical student depends on English, French, and German text-books. But in pharmacology this state of affairs was reversed, and Norway not only has its own text-book on pharmacology, but also the satisfaction of seeing it accepted as a standard work elsewhere. Poulsson was born on April 18th, 1858. After holding various internships at home, he spent three years abroad, studying chemistry under Fresenius in Wiesbaden and pharmacology under Schmiedeberg in Strasbourg. He began to lecture on pharmacology at the University of Christiania in 1891, and four years later was appointed to the chair. In 1928 he retired from this post on reaching the age limit, but he continued active in research till the end, and some of his most valuable work was done quite recently in connexion with vitamins and cod-liver oil at the State Vitamin Institute. Poulsson was also an excellent clinician, and in his early years was the chief medical officer of the Sandfjord hydro. The popularity he enjoyed as much among medical students at home as with fellow scientists at international meetings abroad depended largely on the lucidity of his intellect and his quick grasp of the essentials of any problem with which he was faced. Herein also lay the success of his great text-book which gave the reader the colour and perspective which students do not always find in the writings of their teachers. Poulsson infused some of the same qualities into his lectures. The attention of his listeners was always held by the hope, amounting almost to a conviction, that a flash of wit would give the dead leaves of pharmacology life and substance.

BRITISH ASSOCIATION MEETING AT NORWICH

FOR the second time in its history the British Association for the Advancement of Science is to meet at Norwich, this time under the presidency of Prof. W. W. Watts, who at 8.30 P.M. on Wednesday, Sept. 4th will deliver an address on Form, Drift, and Rhythm of the Continents. The previous meeting was held there in 1868 under the presidency of Dr. J. D. Hooker, botanist and traveller. Sectional addresses will be given during the week that follows by Sir Arthur Smith Woodward (Anthropology) on Recent Progress in the Study of Early Man, by Prof. P. T. Herring (Physiology) on the Pituitary Body and the Diencephalon, and by Dr. Ll. Wynn Jones (Psychology) on Personality and Age. Evening discourses will be delivered by Dr. S. J. Davies on Diesel Engines and by Dr. C. S. Myers on The Help of Psychology in the Choice of a Career. Norwich, although no longer as it was in the Tudor period the second city in the Kingdom, is still the largest city in a purely agricultural district embracing three counties, with a culture and opinion of its own in various branches of art and literature. It is still the "city of gardens" and the new town hall in course of erection is evidence of continued enterprise. There will thus be an agreeable and stimulating background for the meeting. The local hon. secretary is Mr. H. P. Gowen, F.S.A., J.P. General inquiries should be addressed to the Secretary at Burlington House, London, W.1.

THE PITUITARY AGAIN

ON another page of this issue Prof. E. C. Dodds and his collaborators at the Middlesex Hospital describe how they have produced chronic gastric ulcers in animals by means of a pituitary extract. Never before, they believe, have such ulcers been caused by injecting an extract of a normal tissue, and they give reasons for thinking that the apparently large doses given represent no more than an exaggeration of a natural process. If the observations ended here they would be sufficiently striking; but it also appears that the same extract will produce in rabbits a severe anæmia not unlike the pernicious anæmia of human beings. This leads them on to the question whether there is not some hormonal connexion between the posterior lobe of the pituitary gland, the blood picture, and the stomach.

LEARNED EXHIBITS

AT the Conversazione of the Royal Society held at Burlington House on May 3rd there were many exhibits of interest to clinicians. It is impossible to imagine any demonstration that medical science could provide in which essentially physical or chemical methods and apparatus would not play a prominent part. The exhibits of chief medical interest fall into three groups. There are (1) those which have resulted from an approach to some purely medical problem by physical means, (2) those in which medicine has appropriated to its own ends methods and apparatus designed primarily for other purposes, and (3) perhaps of greatest interest, those which give promise of providing clinical science in the near future with new or more refined methods of diagnosis or treatment.

In the first group stand the cathode ray electrocardiograph and the system of cineradiography. The former makes use of a fluorescent screen as the recording element; this has a long after-glow so that the light-accommodated eye is able to view and to examine the completed record for 10 to 12 seconds before it fades. The latter is simple enough to be available as a routine method of examination in the ordinary hospital department; the earlier drawback of prolonged and possibly excessive irradiation of the patient during the taking of a series of exposures has been eliminated by arranging for the X ray tube to be energised intermittently—i.e., each time the camera shutter opens. In the second group we find the ultra short-wave oscillators working on wave-lengths between 2·5 and 6 metres, shown by the General Electric Company. The heating effect of their discharge on several litres of dilute salt solution was demonstrated; they are suitable for medical diathermy and provide a means of generating heat in the deeply placed tissues and organs of the body without immoderately increasing the surface temperature. In the third group may be included a method of continuously measuring small traces of contaminant in a given gas; the ability which it provides of detecting the presence of heavy vapours like hydrocarbons in concentrations of only 1 : 100,000 parts of air may have most valuable applications in the field of the original contention of Marrack and Smith[3] that the amount precipitated is independent of the concentration of non-specific protein in the reacting mixture. Heidelberger and Kendall in 1934, and Dean, Taylor, and Adair[4] this year found that the same amount of protein was precipitated from the antiserum, whether the precipitation took place in one stage or in two; while Heidelberger and Kabat[5] have shown that pneumococci when agglutinated carry down with them from a given amount of antiserum the same amount of protein as is precipitated by the corresponding polysaccharide. These experiments strongly support the theory that this precipitable protein is the actual antibody. This is confirmed by the recovery, from the precipitate formed by pneumococcal polysaccharide and antiserum, of a protein which is active as antibody and can be almost completely precipitated again by the polysaccharide (L. D. Felton, 1932). Breinl and Haurowitz (1930), and more recently L. F. Hewitt[6] have shown that this precipitable protein is chemically indistinguishable from serum globulin.

It is now reported that J. B. Sumner and S. F. Howell, of New York, have prepared the hæmagglutinin of the jack bean as a crystalline protein. In this form, it is stated, it caused perceptible agglutination of dog and cat red blood corpuscles in dilutions up to 1 in 10 million; on human cells it was much less effective, agglutinating them only in dilutions up to 1 in 1000. This protein, however, cannot be considered an antibody, since it occurs naturally—not in response to the stimulus of the introduction of a foreign substance; nor is there evidence that it has the specificity characteristic of most antibodies. Nor are such crystalline agglutinins a new discovery. Edestin will agglutinate sheep and human red blood corpuscles in dilutions up to 1 in 10,000, as was shown by B. White and O. T. Avery as long ago as 1913. Even tannin acting on red blood corpuscles in dilutions up to 1 in 10,000 will reproduce phenomena (agglutination, hæmolysis, complement fixation, and preparation for phagocytosis) resembling those caused by antibodies, though lacking the characteristic specificity (Reiner, 1929). Nevertheless the discovery of a pure protein agglutinin which acts in such extreme dilution may afford valuable information on the mechanism of the action of antibodies.

TUBERCULOUS MILK IN BRISTOL

IN another column Prof. R. H. Parry and Prof. I. Walker Hall, respectively medical officer of health for Bristol and director of the preventive medicine laboratories, tell us of the infected farms in the area from which Bristol draws its milk-supply and which act as reservoirs for the dissemination of bovine tubercle bacilli. Last year 5 per cent. of 485 samples of milk from one area were found to contain virulent bacilli, but it proved possible to track the infection down to 14 farms, the milk from which was intermittently tuberculous over several months. It would indeed have been an achievement if these 14 reservoirs of infection could have promptly been cleared, but the inevitable delay in procedure, of which several striking examples are given, resulted in the supply in one case of known tuberculous milk for three months or more before clearance and the distribution of the herd took place. In two cases the supply was still infected after six months. Profs. Parry and Hall suggest lines of action which would lead to more effective protection of the community and are prepared to justify them as less disturbing to economic conditions than is routine tuberculin testing. That is not the only direction in which Bristol looks for progress. The efforts made in recent years to educate the farmer and dairyman in the production of milk have borne fruit in a uniformly improved standard. This fact is not however widely enough appreciated, for only a few consumers have followed the developments in the industry. The introduction by the Marketing Board of the "milk in school" scheme now offers an opportunity for the diffusion of this information via the school-children to the general public. The preventive medicine and agricultural advisory departments of the University of Bristol are accordingly providing a course of lecture-demonstrations for school teachers on such subjects as production, nutrient values, health and disease in the cow, and the means of increasing the safety of milk and storage of food. Accompanying the syllabus is a brochure on milk as a food, written in simple language as a lesson for children under 12 years, with a supplement for those over 12 years. The children are invited to write essays or make drawings, suitable for posters, upon the subject "A Glass of Milk," and prizes will be awarded to senior and junior boys and girls. The Bristol education committee is coöperating in all these arrangements.

AGRANULOCYTOSIS

IN the last few years there have been many reviews and reports of cases of the peculiar syndrome commonly known as agranulocytic angina, agranulocytosis, or malignant neutropenia. (Since a sore-throat and mouth, though often, is not always associated with this condition, probably the two last names are preferable.) Dr. E. W. Adams has now reviewed "certain aspects" of this syndrome in a report issued by the Ministry of Health.[1] He emphasises the value of pentose nucleotide in the treatment and the importance of amidopyrin in the ætiology. Certain of his statements—some of them lacking exact references—are hardly in agreement with the authoritative review of Jackson and Parker,[2] who have had extensive experience of the disease. Dr. Adams, for example, says that it may occur in children, though they are definitely of opinion that no authentic case has been seen under the age of ten. He also states that the total white cell count is not necessarily lowered, whereas Jackson and Parker and the majority of other workers agree that leucopenia is a sine qua non of the syndrome. In writing on the ætiology of the disease, Dr. Adams does not mention any of the papers describing the pathological findings in hæmopoietic tissues; he is content with the statement under the heading of clinical features, that "after death the bone-marrow is found to be destitute or almost destitute of granulocytes." Many observers, however, have shown that at least in patients dying in the early stage of the disease, though mature polymorphs may be absent, there may be an excess of stem cells; and it was this finding that led FitzHugh and Krumbhaar[3] to make the important suggestion that an arrest of maturation at this level is a key to the ætiology of

PROGNOSIS

A Series of Signed Articles contributed by invitation

LI.—THE PROGNOSIS OF TABES DORSALIS

It is well to regard the prognosis of tabes from two aspects: (1) as regards life, and (2) as regards incapacity.

Expectation of life.—The disease is compatible with 20 or more years of life and thus, in favourable circumstances, need not affect the expectation of life of its victim. Where, however, the original infection has been severe, if tabes develops at all, the interval between infection and development is likely to be short (in years) and the duration of life in such a case will be much less than the average for tabes.

It is significant that while the death-rate from syphilis (per 1000 live births) under one year of age has now fallen to roughly one-third of its pre-war level, and the death-rate from general paralysis has been halved in the same period, doubtless owing to modern therapeutic measures, the death-rate from tabes still remains much where it was; it now averages about 19 per million of the population, as against 21 before the war. The incidence of tabes in men is about ten times what it is in women. About 10 per cent. of syphilitics develop nerve syphilis, and less than half of these are tabetics. There will be general agreement that the incidence of tabes has been reduced in recent years, but as the duration of the disease so greatly exceeds that of general paresis, the death-rate takes much longer to show an improvement.

Incapacity.—The form of incapacity varies—all the disabling features are not found concentrated in any one case, however severe the infection may have been in the first place. The two main groups of disability are those affecting (*a*) eyesight, and (*b*) locomotion. It is noteworthy that even a definite optic atrophy may be stayed in its progress if detected early, and efficient treatment in the nick of time may save for the patient at least a modicum of vision.

IMPORTANCE OF EARLY DIAGNOSIS

The outlook in a given case of tabes dorsalis depends very largely upon an early diagnosis, followed by efficient and vigilant treatment. Thus much depends on the intelligent interpretation of a suggestive sign or symptom—it may be shooting pains, a perforating ulcer under one great toe, a difficulty in beginning to urinate, the presence of cystitis, the sudden appearance of a squint, or the accidental discovery of a single sluggish pupil or of unequal pupils. The prognosis of the individual case depends on whether full investigation and intensive treatment follow immediately. On the other hand, a diagnosis of tabes must not be accepted without verification. Many of us have been told that knee-jerks are absent when they are in fact present, albeit difficult to obtain. In this connexion it should be remembered that ankle-jerks are always lost first, and if they are retained in any case the apparent absence of knee-jerks need not cause alarm.

ARREST IN ADVANCED CASES

It is often stated that a case of tabes should never be allowed to reach the ataxic stage. This is true, but should not be taken to mean that if ataxia has begun to show itself treatment will certainly not be effective. Except in those rapid cases which follow a year or two after the original infection, where the prognosis is always hopeless, there is a good chance of improvement even when ataxia is manifest. But no treatment can benefit a blindness, already absolute, from optic atrophy, though I have under my observation at the moment a woman in whom the progress of the atrophy has been stayed and some degree of vision preserved following efficient treatment. I have had more than one case in which a single Argyll Robertson pupil has again become reactive to light. There are suggestions that the optic atrophy case just referred to may become mental, a point which suggests the necessity of bearing in mind the fact that tabetic psychoses occur as well as taboparesis; and the prognosis of the one is very different from the prognosis of the other. Just as a "leg" tabes will not go blind, so, as a general rule, an "optic" tabes will not later develop any ataxia. There is no stage in any case of tabes at which "arrest" may not occur. If, as I have said above, early onset of tabetic symptoms after infection means as a rule a rapid course, late onset, always presuming that we can exclude taboparesis, means a slow one. But in these cases expectation of life must to some extent differ with social status. A poor patient cannot so easily maintain his general condition, so as to prevent intercurrent infection, as can a prosperous one. Ascending infections of the genito-urinary tract make quicker headway and occur more often in the poorer type of patient. A well-to-do man with "leg" tabes may, as is well known, go about for years in a wheel chair, mentally very alert, beating everyone at bridge, and having no other disability save that of locomotion.

RE-EDUCATION: CRISES

There is no limit to the duration of the pre-ataxic stage, and some cases never go beyond it. Here re-education may work wonders in postponing or preventing the onset of developed ataxia. The various crises are never fatal at the time, and it has been said that they do nothing to shorten life. This has not been my experience. In some, crises seemed to herald an advance of the disease; in others the general resistance to infection had been so diminished that an ascending urinary infection was soon fatal. This was so, for instance, in one man with gastric crises which failed to respond to chloretone; morphia had to be given, eventually in very large doses, and for so long that debility and cachexia became pronounced. Another of my intestinal crises cases, having survived the attentions of a surgeon who had treated him as an acute abdomen, and having got through subsequent attacks aided by medical treatment, in the end died of apoplexy. An elderly patient becoming bedridden as the result of the collapse of a limb following a Charcot's joint may soon die from extensive bedsores, and the same result may occur where a case of tabes is associated with a fracture due to fragilitas ossium. Evidence of syphilitic aortitis is not a discouraging feature.

URINARY INFECTION

A rule of treatment upon which the individual prognosis depends more perhaps than any other is regular testing of urine and examination for retention with overflow. The patient may not complain of industrial hygiene. The use of phenolic and basic synthetic resins for the purification of water was demonstrated; they reduced both acidic and basic dyestuffs to insignificant traces, and they removed completely all the saline contents of sea water to give drinking water.

In a lecture on Dr. Robert Hooke, F.R.S., Mr. Walter Adams reminded us that July 18th of this year is the tercentenary of his birth. Side by side in another room were demonstrated Hooke's own microscope and the earliest existing photograph, taken just 100 years ago, by Fox Talbot. These two centenary exhibits are the original products of developments in physics and in chemistry to which clinical medicine owes more than can be summarised and without which medical science would be non-existent. It would perhaps have emphasised their importance and certainly have added to their dramatic value to have shown alongside these two early exhibits of photography and microscopy the two latest developments of photomicroscopy which were demonstrated: an apparatus for making stereo-micro-photographs and a twin film polygraph and strobograph for recording the very rapid and fugitive movements of the smallest animalculæ. Dr. Adrian's demonstration of the Berger rhythm aroused great interest. Using himself as the experimental subject, the resting rhythm was clearly and regularly seen after projection of the oscillograph tracing on a large screen by means of an epidiascope; the abolition of this rhythm brought about by visual stimulation, by mental effort of an unusual degree, and by unexpected cutaneous stimulation occurred regularly. The results so far achieved have been already commented upon (see THE LANCET, Jan. 12th, p. 96), but although no new results were communicated or demonstrated Dr. Adrian provided a model demonstration with an adequate and very clear introduction.

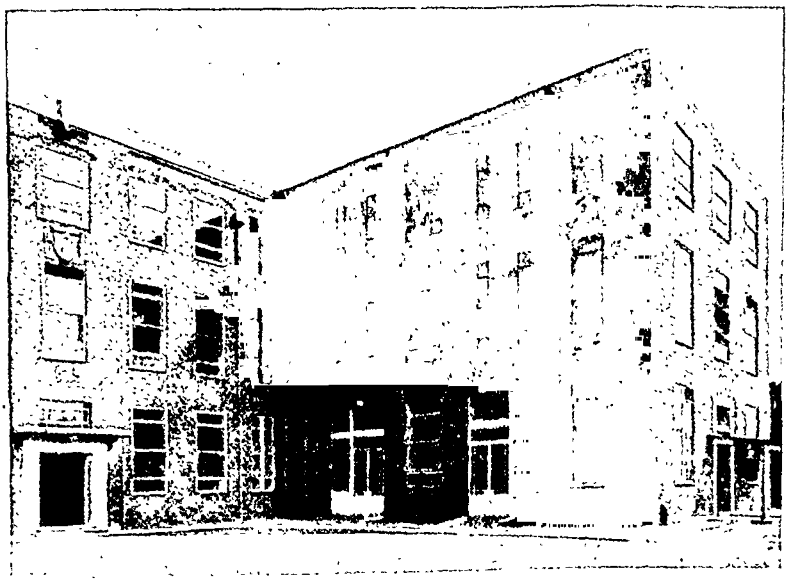
Another popular exhibit was that of some apparatus used in research into the psychological and physiological qualities necessary in motor drivers. The subject examined sits in a small motor-car, hanging in front of which is a screen upon which a cinematograph film of a model landscape is projected; the normal controls of the car control the position of this landscape on the screen and its apparent rate of approach. Movements of the car in relation to the surface of the road depicted in the landscape are automatically recorded, and from this record may be obtained a measurement of the reaction times of the driver when faced with different problems in car management. Since the time factor is one which enters so largely into intelligence testing and other forms of examination for mental ability, it seems likely that this form of test could be adapted to problems less specialised than that of car driving and might be made the basis of assessing vocational ability along many different lines.

Sir Edmund Spriggs will deliver the Croonian lectures of the Royal College of Physicians on May 14th, 16th, and 21st. His subject will be a Clinical Study of Headaches. The lectures will take place at the College at 5 P.M., and any member of the medical profession will be admitted on presentation of his card.

Surg.-Captain Sheldon F. Dudley took up his duty on May 1st as deputy director-general of the Royal Navy from the R.N. Hospital at Chatham. He was formerly director of medical studies and professor of hygiene, pathology, and tropical diseases at the R.N. College, Greenwich. In his Milroy lectures delivered in 1931, he drew some lessons of the distribution of infectious diseases in the Royal Navy; his success in limiting the spread of infectious disease at Greenwich Hospital School is common knowledge.

SOCIETY OF PUBLIC ANALYSTS.—At a meeting of this society held in London on May 1st, Dr. G. Roche Lynch and Mr. R. H. Slater, D.Sc., described a putrefaction product of toxicological significance. A crystalline para-phenylpropionic acid was formed by anaerobic putrefaction in a body which had been buried in an unsealed lead coffin, and had consequently lain for a considerable time under water without exposure to the air. This compound was extracted with ether from the acid aqueous liquid obtained in the Stas-Otoo process, and until its identity was established it was suggestive of the presence of one of the barbituric acid derivatives. Dr. Roche Lynch and Dr. Slater also reported on the toxicological examination in a fatal case of poisoning by meta fuel.

BRITISH POSTGRADUATE MEDICAL SCHOOL



THE accompanying photograph shows the entrance to the new out-patient department of the Hammersmith Hospital of the London County Council attached to the British Postgraduate Medical School, which is to be opened by H.M. the King on Monday next. The block of buildings, comprising school and out-patient department, makes up the east wing of a teaching hospital of 400 beds which is to be devoted solely to post-graduate medical education. Chairs of medicine, surgery, midwifery, and pathology in London University have been established at the school. In a recent issue (THE LANCET, April 7th, 1934) we reproduced detailed plans of the medical school and of the new surgical and maternity block, and we propose to give in an early issue an illustrated account of the equipment and system of teaching at the school.

rules by which the diagnosis of influenza will be justified, though it may be permitted him to point out certain difficulties and plead for a more refined and intensive clinical analysis of cases of the influenza type. I propose rather to consider here certain experimental facts which have been accumulated during the last three years, and which appear to me to show that it should become possible in the future to separate with precision epidemic influenza from other diseases which simulate it.

It is clear that if the cause or causes of influenza could be identified with certainty a great step would have been made in this direction, and I believe it is now being gradually proved that the *primary* infective agent in epidemic influenza is a filtrable virus. It is with this aspect of the subject that I propose to deal. It must not be supposed that the bacteria which have been cultivated from cases of influenza are of no significance in the human disease. There is a great deal of evidence which shows that the visible bacteria are very important in particular cases, and it should be stated that Pfeiffer's bacillus or *Hæmophilus influenzæ* is still regarded by many observers as the prime cause of the disease and many of its complications. I shall not go into this question in detail, but if a virus is proved to be present in the early stages of influenza infection it seems to me that the visible bacteria, including Pfeiffer's bacillus, must be regarded as secondary invaders of tissues damaged by the action of the virus.

The Virus Hypothesis

It was suggested about 1914 that influenza was really a virus disease. At that time knowledge of viruses was meagre, and although we know much more to-day about virus diseases we do not yet know a great deal about the viruses themselves. The view with the greatest following at present is that viruses are exceedingly small micro-organisms with very strict parasitic habits. The small particles which can be demonstrated in suspensions of viruses are so minute that special methods are required for their elucidation, but it does seem that we are gradually getting to know something of the shape and form of virus particles. The parasitism of many viruses is so strict that they will only grow in one or two species, and sometimes show a striking preference for certain tissues of the host. They cannot be cultivated, with perhaps one or two exceptions, on artificial media apart from living cells.

The virus hypothesis for influenza postulated, therefore, that the infective agent was so small that it could be separated from visible micro-organisms by filtration, that it was most probably an obligate parasite incapable of growth except in the animal body and that the parasitism might possibly be so strict that it would grow and cause disease only in man.

This hypothesis became prominent during the pandemic of 1918–19, for at that time a number of workers ventured to question the claims of *H. influenzæ* to the rôle of principal villain in the drama of influenza, although this organism had held an almost undisputed position since the end of the pandemic 1889–90. There was not much experimental evidence in favour of the virus theory at this time because no one knew of an experimental animal which was susceptible to infection with human influenza. Recourse was therefore made to human volunteers. Nicolle and Lebailly (1918) and de la Rivière (1918) record what appeared to be successful infections with bacteria-free filtrates of material from influenza patients. Yamanouchi, Iwashima, and Sakakami also appeared to be successful in a larger series of experiments. But against these must be placed the negative results of MacCoy, Rosenau, and others (1921), Friedberger and Konitzer (1919), Lister and Taylor (1919). All these experiments on human volunteers are of very doubtful value. Man is an exceedingly bad experimental animal and almost useless when he is used for experiment during an epidemic. One can never be sure that the experimental subject is susceptible and therefore negative results can be discounted; while positive results, though perhaps more significant, are always open to the suspicion that infection was picked up in some accidental manner. On the other hand, in the absence of an epidemic there is no supply of virus to test on presumably susceptible subjects.

The Ferret Susceptible to Influenza

In 1933 Smith, Andrewes, and I began to hope that we had discovered a method of studying influenza in laboratory animals. We found that it was possible to transmit a disease to ferrets by inoculating intranasally filtrates of pharyngeal washings from cases of epidemic influenza in man. The filters we employed were Gradocol membrane filters made and supplied by our colleague, Dr. Elford. They had an average pore size sufficiently small to keep back all visible bacteria, and as far as we could determine, the filtrates we used were bacteriologically sterile. We obtained 5 successful transfers from 8 cases of "influenza" and then the epidemic disappeared. Subsequent to this, throat-washings from sporadic cases diagnosed as influenza and from normal subjects failed to infect ferrets, and nasal secretions from cases of "common cold" were also without effect. The disease in the ferrets was of varying severity and would pass from a sick animal to a healthy one by simple contact, in other words the experimental disease was contagious.

Isolation of experimental ferrets.—Experience with dog distemper had shown us that somewhat elaborate precautions were necessary to prevent the accidental spread of any highly infectious disease, and we immediately adopted the scheme of rigid isolation which was evolved for the work on dog distemper.

The plan is to house all experimental animals in a special building which can only be entered through a passageway, the floor of which is constantly covered with a lysol bath three inches deep. All workers therefore wear rubber boots and rubber overcoats. On entry into the building boots and coats are washed down with lysol. There is a central hall round which are a number of cubicles, each of which is completely separated from the others and from the central hall. Each experimental ferret is placed in a special cage and the cage in a cubicle. Before entry into a cubicle the worker or attendant is swabbed down with lysol so that any infectious material, dust, sprayed droplets, &c., sticks to the damp surface and is subsequently sterilised by the lysol wash which follows on emergence from the cubicle.

A routine of this kind is very irksome and it slows down the work enormously, but if the ritual is carried out faithfully we can be confident that the experimental animals are safe from accidental cross-infection from one to another. In addition to being cumbrous the method is costly, for a special building is required and a reliable staff of attendants. Lack of adequate accommodation such as we desired compelled us to abandon some of our original strains and work more intensively with one in particular. This strain was recovered from one of the team (W. S.) who contracted influenza soon after the investigation was under weigh. There is no proof, but it is quite possible discomfort and one may have no idea that any urinary trouble has begun. But unless the condition is discovered early and efficiently treated, urinary infection takes place and the patient goes downhill rapidly. In the same way severe bone disease and foot sepsis may occur before a perforating ulcer, being anæsthetic, has been noticed.

LABORATORY FINDINGS

The inferences one is justified in drawing from laboratory findings as regards prognosis deserve notice. In a doubtful case the assurance that the blood Wassermann is negative is not enough. We must be sure that there is no pleocytosis of the cerebro-spinal fluid, for this is a constant and a very early sign of tabes. The cerebro-spinal Wassermann is positive in over 75 per cent. of cases if 1 c.cm. of fluid is used; this is a rather larger figure than the percentage of blood-positive Wassermanns. An early change to negative under treatment is of good omen. A diminution in the lymphocyte count of the cerebro-spinal fluid under treatment is also a good sign, and is the easiest change in laboratory findings to obtain; whilst a high pre-treatment count suggests that treatment is worth while and prognosis relatively good. A diminution of cerebro-spinal protein under treatment is a favourable sign. The globulin, however, is much less likely to alter under treatment. A colloidal gold curve which is luetic in type (0014320000) is also favourable, a paretic curve (5555443200) being of course the reverse. Where arrest takes place there may be no curve, and the cerebro-spinal fluid may become normal again. It must be remembered, however, that even in a tabes which is clinically advancing the blood and even the cerebro-spinal fluid may come to yield and to continue to yield a negative Wassermann. If either or both (blood and fluid) become negative in a case in which they have been previously positive six-monthly tests must be done, and the signs and symptoms must always be regarded as over-riding any tests from the point of view of prognosis.

TABOPARESIS

It is absurd to assume that because a patient with tabes does not at the onset suggest taboparesis he will never at any time develop paretic symptoms. If such symptoms do appear then, even with malarial treatment, which is not so successful here as in ordinary general paresis, the patient is not likely to survive more than, at the most, four years. It is just as important to be on the look-out for the development of taboparesis as it is to watch for urinary infection, pulmonary tuberculosis, influenza, or pneumonia, any of which may be insidious in onset or development. The full examination of the cerebro-spinal fluid may here be the only sure guide.

The warning not to confuse psychoses with taboparesis has already been given. Juvenile tabes progresses fast if it develops early, slowly if it comes on late, unless it is aggravated in its progress by an acute infection or by an accident. Similarly with conjugal tabes. It is just as worth while to treat juvenile tabes efficiently as it is the adult form. Alcoholic tabetics do badly, and the disease progresses rapidly.

In all forms and at all ages the maintenance of the general condition is of cardinal importance to the prognosis. Next to this comes the success with which re-education can be achieved.

EPIDEMIC INFLUENZA: A VIRUS DISEASE.*

BY P. P. LAIDLAW, F.R.C.P. Lond., F.R.S.

INFLUENZA is one of the greater scourges of mankind. In epidemic form, on many occasions, it has spread throughout the world causing incalculable damage. For example, the pandemic of 1918–19 is estimated to have involved 500,000,000 people and cost the world upwards of 15,000,000 lives. Previous to this (e.g., 1889–90 and 1836–37) other pandemics of corresponding magnitude had taken their toll of humanity. Between the great pandemics, often following them closely, lesser outbreaks have occurred from time to time, involving a country or a part of it, a barracks or a school. In addition to these patches of localised infection there are sporadic cases of disease which are often diagnosed as influenza; but we have no assurance that these sporadic cases are really the same disease and have the same ætiology as the epidemic cases. It is, in fact, very doubtful if they always are, and I, for one, feel that many of these cases would be better labelled with the old war-time diagnosis, honest if non-committal, P.U.O., or pyrexia of unknown origin. Further, we have no proof that the different epidemics are due to one and the same cause; there are indeed difficulties in the way of accepting this view literally. Yet there is such great similarity in the spread of the disease and the symptoms recorded for different epidemics and pandemics that it seems fairly certain that if there are multiple causal agents these must be close relatives and connected in some way.

Epidemic influenza is characterised by great infectivity with rapid spread in a population, a short incubation period of about 48 hours, a very sudden onset with fever, malaise, and depression, passing on to prostration. Pains in the head, back, or limbs are common. A coryza and some pharyngitis can usually be detected. After a few days' fever, in the majority of cases, recovery sets in and the temperature subsides to normal; but there is left behind a condition of depression and weakness quite unexpected in view of the short period of fever and the slight physical signs. In a proportion of cases tracheitis, bronchitis, and broncho-pneumonia may develop when the *mortality-rate rises steeply*. During an epidemic the diagnosis is relatively easy, for many severe as well as mild cases are seen; and all stages of the disease may be observed on one day. There is, moreover, ample evidence of great infectivity. But in sporadic cases where evidence of infectivity is lacking and the symptoms are often milder it may be impossible to reach a sure diagnosis. Again, at the beginning of an epidemic or in the early stages of the disease, it may be very difficult to diagnose a case with confidence.

It is not the province of a pathologist to discuss the clinical aspects of the disease or to lay down

that he became infected from the experimental animals. It is suggestive that his illness developed at a time when the epidemic had almost disappeared and chances of outside infection seem to have been remote.

The virus.—The infecting principle is abundant in the nasal mucosa of sick ferrets, and for routine supplies of virus the diseased mucous membrane is ground in a mortar, emulsified with saline, and the resultant suspension is centrifugalised. The opalescent supernatant fluid is rich in virus and contains small numbers of visible bacteria, which may be eliminated if desired by filtration through a suitable membrane filter. Infective filtrates have been specially examined for the small filter-passing organism *Bacterium pneumosintes* of Olitsky and Gates (1921) because this small organism was believed by the two discoverers to be the primary infective agent of influenza. We have never encountered it. Inoculation of culture media, suitable for the multiplication of *B. pneumosintes* with our virus followed by incubation, results in total loss of infectivity. The virus has, in fact, not yet been cultivated on artificial media. It is destroyed by heating to 56° C. for an hour and it will withstand drying or storage in glycerol for many weeks.

A remarkable feature of this virus is the fact that it will only infect through the respiratory tract. Subcutaneous, intravenous, intraperitoneal, or intracerebral inoculations are without effect. Again, the virus can only be recovered from the respiratory passages or lungs. Blood, cerebro-spinal fluid, liver, spleen, and brain do not appear to contain any virus, even at the height of the disease.

The facts are very remarkable. Virus can be recovered only from the nasal mucosa and the lungs which are, after all, surface structures; it cannot be recovered from the deeper tissues. Yet it is clear that the virus or its products does invade the body, as is shown by the symptoms of disease and the production of circulating antibodies. What may be the explanation of the facts we do not know, but they help to differentiate the virus from others, and they must be taken into account when considering the full explanation of the disease.

Influenza in the ferret.—The virus disease in the ferret is characterised by an incubation period of about 48 hours followed by fever in which the temperature may reach 107° F. This is followed by a remission and thereafter a second febrile period usually lasting three or four days, during which there are symptoms of nasal catarrh, such as sneezing, nasal obstruction, mucopurulent discharge from the nose, and sticky accumulations round the nares. Throughout the illness, but varying greatly from case to case, there is prostration and occasionally signs of muscular weakness. The disease is never fatal when ferrets are inoculated without an anæsthetic. Certain strains of streptococci in conjunction with the virus do produce a more severe disease and prolong the illness, but do not cause a fatal outcome. Hæmophilic organisms from ferret, pig, or human beings do not appear to modify the disease materially.

When the intranasal instillation of virus is made, in series, into ferrets which are anæsthetised with ether (Shope, 1934) pneumonia develops in the inoculated animals. Without an anæsthetic the recently isolated human strain of virus never causes pneumonia, but after passage through many ferrets pneumonia may occur. The cut surface of the solid lung is usually bacteriologically sterile, and emulsions of solid lung, though rich in virus, are usually free from bacteria, and there is no doubt that the virus by itself can, and on occasions does, cause a characteristic pneumonia.

Sections of the nasal mucosa, from ferrets killed in the later stages of the disease, always show signs of acute inflammation, vascular engorgement, dilated lymph channels, catarrh of the superficial epithelium, loss of all ciliated cells, and collections of mucopurulent exudate in the air spaces. Many polymorphonuclear leucocytes can be seen on their way through the remains of the epithelium. Inclusion bodies have not been detected.

Immunity.—Ferrets which have recovered from an attack of the disease are immune to further infection for a few months, but after six or seven months they gradually become susceptible once more. Reinfection at about this time leads to a sharp febrile attack with the usual symptoms of the primary attack, but the second attack is usually milder and of shorter duration than the first.

Serum from a convalescent ferret contains antibodies to the virus. These may be demonstrated by mixing virus and serum together and allowing the mixture to stand at room temperature for ten minutes and then instilling the mixture into another ferret's nostrils. Normal ferret serum has no neutralising power. Convalescent human serum, and in fact most human sera, also contains antibodies for the virus; indeed, we have only found two human sera which fail to neutralise when mixed with virus. It has been found to be possible to prepare antiserum in bulk by oft-repeated subcutaneous injection of virus into horses and to demonstrate its potency by admixture of serum with virus as just described for ferret serum.

Influenza in Mice

In 1934 we discovered that the virus from ferrets could be adapted to mice. This means that it was found possible to infect mice when ferret virus was instilled into the nostrils of mice which had previously been anæsthetised with ether. In the first group of mice so treated only a small proportion showed signs of infection. Inoculations with material from the sick mice to others, however, led to more regular infection and a more serious disease. After several transfers the virus infected nearly 100 per cent. of mice and induced an illness which was very often fatal. The disease in mice is essentially a pneumonia which spreads from the larger bronchi to the periphery of the lung, and in fatal cases the process results in almost complete hepatisation of the lungs.

I do not propose to enter into a consideration of the histological changes which are to be found in the pneumonic lung. For our present purpose it is sufficient to point out that the cut surface of the solid lung is usually sterile, and that small fragments of solid lung, on incubation in culture media, often show no growth of visible bacteria. The organisms which are occasionally encountered are of different types and can have no causal relationship to the disease process, since they can be filtered off and typical infection produced by the filtrates. In the mouse, then, as in the ferret, pneumonia may be produced by the virus, and in the mouse this pneumonia is frequently fatal.

The upper parts of the respiratory tract of mice do not seem to be susceptible to attack by the virus as is the case in the ferret. The nasal mucosa, for example, appears to be unaffected even in fatal cases. Corresponding with this there is no sneezing, and as mice do not cough dissemination of the disease does not occur. It is thus possible to conduct experiments on mice without the elaborate isolation precautions and perhaps muscle tenderness, cough, and a laboured jerky breathing. The duration of the disease is short, usually from 2–6 days, and apparent recovery is almost as dramatic as the onset. Fatal cases show, according to Shope (1931) "an extremely œdematous type of broncho-pneumonia."

The analogies with human epidemic influenza are very striking. In both we have high infectivity and rapid spread of the disease, short incubation period, sudden onset, high fever, prostration, muscular weakness, cough, and in fatal cases extensive pathological changes in the lungs. The ætiology of this disease remained obscure for some years, but Shope (1931, 1932) succeeded in demonstrating in a series of brilliant researches that this pig disease is a complex; and results from a dual infection with (*a*) a filtrable virus which by itself is almost harmless for pigs, and (*b*) a special hæmophilic organism, *Hæmophilus influenzæ* (*suis*), which alone is powerless. Infection with a mixture of virus and bacillus regularly produces a serious and sometimes fatal disease in susceptible pigs. Now, the filtrable virus from the pig disease will infect ferrets, as shown by Smith, Andrewes, and Laidlaw (1933), confirmed by Shope (1934), and produce in them a disease which is almost indistinguishable from the disease caused by the human strain of influenza virus. There is a similar short incubation period, the same type of fever, almost identical symptoms and precisely analogous changes in the nasal mucosa. On the whole, the porcine strain of virus seems to be more virulent and, in the earlier transmissions, possess a greater affinity for ferret lung tissue. Ferrets which are immune to one strain of virus are always resistant and sometimes immune to the other. Mice, under light ether anæsthesia, can be infected with the porcine strain and show lung lesions which are indistinguishable from those following infection with the human strain.

Immune sera can be prepared in ferrets and horses, and tests of these sera on ferrets and mice prove that the two viruses have some antigenic elements in common, but also possess different constituents.

DISCUSSION

The significance of these results is very great. Shope has proved, for the pig, that the combination of virus plus hæmophilic organism is much more potent than was to be expected from summing the mild diseases caused by the two agents acting separately. By analogy it seems highly probable that a similar state of affairs will also hold for man. Under this view the virus alone would cause the milder uncomplicated cases of influenza of short duration, which are so common during epidemics, and that dual infection with virus plus hæmophilic bacilli would be responsible for cases with complications such as sinusitis, purulent bronchitis, broncho-pneumonia, &c. If the secondary invader were varied or there were more than one, many of the remarkable bacteriological findings in cases of epidemic influenza of the past would be adequately explained. The proof or disproof of this conception of the disease in man must await intensive study of complicated cases during an epidemic.

But there is more than this to be gained from a consideration of the swine influenza virus and its activities. As we have seen, the pathogenic activities of human and porcine strains of virus are very similar for ferrets and mice. Are they similar for pigs? In 1933 my two colleagues and myself attempted to infect pigs with our 1933 strain of virus from man, but without success. Quite recently, however, Elkeles has informed us (private communication, 1935) that he has achieved successful results. He concludes: "That the virus obtained by Smith, Andrewes, and Laidlaw from influenza patients when inoculated, especially in combination with *H. influenzæ*, intranasally to young pigs, is able to produce in them clinical and pathological symptoms of a characteristic disease." The symptoms he records, and the post-mortem appearances he describes, are similar to those recorded by Shope for experimental swine influenza. If Elkeles's results could be extended to show that it was possible to produce a disease in pigs with human virus which was capable of inducing a typical epizoötic in hogs, the pathogenic similarity between the two virus diseases would be complete; but the facts as they stand are significant enough.

We have two viruses of different origin capable of causing similar diseases in three species of animals—ferrets, mice, and pigs. These two viruses have been shown to have certain similar antigenic constituents as well as certain different ones. The conclusion seems inevitable that the viruses are really close relatives, and Koen's view regarding the ætiology of "hog flu" becomes more than plausible. It seems to me, indeed, exceedingly probable that the virus of swine influenza is really the virus of the great pandemic of 1918 adapted to the pig and persisting in that species ever since. Adaptation of a virus to a new species has been accomplished experimentally again and again in virus diseases. It appears to consist merely in an alteration in the aggressiveness of the virus for the new host. This important modification of virus activity has not yet been shown to be associated with alteration in the antigenic structure of the virus. If our conclusion is justified it would mean that the virus of the 1918 pandemic, though closely allied to that now current in the human population, was really slightly different. This very difference between the two strains of virus gives us a possible explanation for the pandemic.

At some time or place a variant of the current influenza virus appeared and this variant might be expected to flourish in a population which was resistant to the parent strain. It is not quite the same thing as a new virus attacking a fully susceptible population, but if the variation were great enough the result as to spread and attack rate might approximate to this and the resulting epidemic might become world wide.

Similar arguments might be made for the other pandemics, and it is quite possible that all pandemics may be due to the occurrence of variants of one type of original virus. The argument is highly speculative but plausible. Proof could only be obtained from an intensive study of viruses from many epidemics and pandemics, and comparing the properties of viruses which are isolated from time to time and place to place. Some further light may come on this question from the work now in progress by my two colleagues on the antibody content of human serum against the human and porcine strains of virus, for the antibody content of a serum may be taken to indicate the past history of the donor and whether he has been exposed to a given infection or not. The future must decide whether the results prove valuable.

I have tried to indicate the lines of work and some of the results which emerge from the modern study of epidemic influenza, and to give grounds for my conviction that the primary infective agent in this disease is a filterable virus, and, further, to show that there is room for an adequate explanation of the pandemics as well as the epidemics under the virus theory.

in Porto Rico. "In its clinical course it appeared to be typical epidemic influenza though the mortality was low." Specimens of sputum from selected cases were sent to Dr. T. Francis, Jun., of the Rockefeller Hospital in New York. During the winter of 1933–34 Francis had tried, without any success, to infect ferrets by intranasal inoculation of material from a number of diseases, including examples of the "common cold" and two cases of clinical influenza. Three of the specimens from Porto Rico were inoculated intranasally into ferrets under ether anæsthesia. On the second day after inoculation each of these three ferrets developed fever. One of the ferrets was killed on the third day, and an emulsion of the nasal mucosa and the lungs was made. The emulsion was filtered through a Berkefeld V. candle, and it was found that the bacteria-free filtrate, when inoculated intranasally, induced disease in another ferret. After the sixth passage pneumonia always developed in ferrets which were inoculated under ether anæsthesia. From Francis's description of the disease in his ferrets, the course of the fever, the symptoms, and the post-mortem appearances, there was no doubt that he was dealing with a disease very similar to that described by us in 1933. One of Francis's laboratory attendants developed clinical influenza early in the course of these researches. From the attendant Francis recovered a virus with similar properties to those shown by the Porto Rico strain, though there appeared at first to be some differences. Francis also discovered, independently, that mice could be infected with the virus from ferrets and that a fatal pneumonia might ensue.

On the whole it seemed that the Porto Rico virus was more vicious than the English one, producing more extensive lesions in the lungs of ferrets and killing mice more rapidly. We were naturally thrilled when we learned of Francis's success with an epidemic in another part of the world, and we sent him a small supply of the specific antiserum prepared in a horse. Imagine with what impatience we awaited news of the result of his tests to determine whether the Porto Rico strain was really identical with our strain or whether it would prove to be different in some way.

The results of these tests have not yet been published, though they are expected to appear in the very near future. Dr. Francis has given me permission to state that the Porto Rico strain appears to him to be identical with ours and, *further*, that the strain he secured from the Philadelphia outbreak about January, 1935, is also of the same type. Dr. Francis has also generously sent specimens of these two viruses to us, and our results, so far, are in complete agreement with his.

SUMMARY

Summarising the results to date we may say that virus has been isolated on several occasions from epidemic influenza cases in man, capable of infecting ferrets and mice and producing characteristic diseases in both species. All strains of virus are neutralised by one specific antiserum. The virus is therefore one, and it has been obtained from cases in London 1933, London 1934, Shorncliffe 1935, London 1935, Porto Rico 1934, and Philadelphia 1935. The evidence is thus accumulating rapidly in favour of the virus hypothesis. In fact it appears to me already transformed into a theorem which in the future will be capable of demonstration.

We must not, however, lose sight of the fact that much remains to be explained; the sporadic cases are a difficulty, and the collection of cases at Woolwich from which we failed to recover virus remains mysterious. It may be that we are inclined to lay too great emphasis on the negative results following inoculation of ferrets with material from cases diagnosed as influenza. Failure to infect a ferret may merely mean that there was an inadequate concentration of virus in the material collected from the patient (the total amount of virus collected by washing a mucous membrane with saline is probably small), or that such virus as was present lacked aggressiveness for ferrets. To put it in another way, it may be that man is a much more sensitive test-object than a ferret for influenza virus. If this were so the clinical diagnosis might represent the truth more nearly than the ferret test we have used. We do not know.

Further, if there is only one influenza virus, it will not be easy to account for the periodic appearance of the great pandemics which have, from time to time, spread over the world. There are probably several factors concerned in the production of epidemics and pandemics, but of these the resistance or susceptibility of a population to infection must be very important. The passage of an epidemic leaves behind the more resistant of the population; some do not contract the disease because they are resistant from the outset, others contract the disease, recover, and are probably immune for a time. Repeated epidemics of one type should result in a resistant stock. If the human population has been repeatedly and frequently exposed to infection by this particular influenza virus, it is not easy to understand how a pandemic due to the same virus can develop.

Swine Influenza

Let us turn, however, to another set of observations which have a bearing upon our main problem, though at first sight they may appear to be of smaller importance. Consider the epizoötic disease known as "hog flu," or swine influenza. Swine influenza did not occur, or perhaps was unrecognised until 1918. Dr. J. S. Koen, then an inspector in the division of hog cholera control of the Bureau of Animal Industry in the United States of America, was greatly impressed, first, by the simultaneous prevalence of human influenza and the new disease of hogs, and, secondly, by the resemblance of the symptoms seen in man to those occurring at that time in pigs. He concluded that the two diseases were the same, and gave the name of "flu" to the new disease of hogs. Koen's view did not meet with general acceptance but the name was considered suitable, and the disease has persisted intermittently ever since. It is to-day a serious disease for the farmer who raises pigs on a large scale in the United States. Dorset, McBryde, and Niles (1922) record a typical but unusually severe outbreak in a herd of 102 young pigs.

> On Dec. 3rd the herd looked normal. On the 4th the farmer first noticed symptoms of sickness. "On Dec. 6th 11 had died and the entire remainder of the herd was so sick that they could be walked among and even kicked without forcing them to move." The severe state of illness remained practically unaltered until the sixth day of illness when there was a remarkable improvement, "almost all of the entire herd was up and eating." Full restoration of health and bodily condition was a slower matter. In this outbreak the mortality was about 10 per cent. It is usually about 2 per cent., though in very exceptional instances it may reach 25 per cent.

The symptoms of swine influenza are fever, when the temperature may reach 105° or 107° F., anorexia, profound prostration, apparent muscular weakness, thinks, if it were accompanied by proper supervision in the streets and suspect quarters to which prostitutes would shift when expelled from the public brothel. It would also be necessary to conduct a carefully organised campaign in favour of better morals.

SCOTLAND

(FROM OUR OWN CORRESPONDENT)

TOBACCO AMBLYOPIA

At last week's meeting of the Edinburgh Medico-Chirurgical Society Dr. H. M. Traquair read a paper based on his long experience of tobacco amblyopia. He pointed out that the ganglion cells of the retina or their fibres are extremely susceptible to the action of toxic substances. Some of these affect the peripheral cells, but the majority affect the central cells or fibres, and thus interfere with central vision. Most of the toxins which cause central visual defects also cause peripheral neuritis; but tobacco is an exception. Only the visual elements distal to the chiasma are susceptible, and it is probably the ganglion cells alone that are concerned in all types of toxic amblyopia.

Tobacco belongs to the group of poisons which affect the central nerve elements of the retina. The poison may be absorbed by smoking, chewing, snuffing, or eating tobacco, so that the toxic substance is not necessarily a distillation product. The smoking of a large number of cigarettes usually brings on gastric or cardiac symptoms before amblyopia develops; but if a pipe is smoked, or if the patient chews tobacco, amblyopia may be pronounced while other symptoms of tobacco poisoning are slight. An average of 84 cases of tobacco amblyopia are seen every year at Edinburgh Royal Infirmary, and these constitute 1 per cent. of all eye cases attending the out-patient department. In the past twenty-two years, 1856 cases have been seen in the Infirmary, of which all but 8 were in males. Most of the patients have been between 45 and 65 years of age, and the amount of tobacco consumed has varied from ½ oz. to 9 oz. a week, the average being just over 3 oz. The smallest quantity of cigarettes producing amblyopia was 70 a week.

The clinical diagnosis, Dr. Traquair said, can be made with certainty if proper methods of examination are used. The patient is usually between 50 and 60 years of age, and complains that he is unable to recognise the faces of his friends in the street, or that there is a mist between him and everything he looks at. He is surrounded by a peculiar heavy odour of stale tobacco which indicates the pipe-smoker. Vision may be depressed to 6/60, but may, to the black-and-white test card, be 6/6 to 6/18. The use of Bjerrum's test card which has grey letters on a grey background demonstrates the visual defect much more easily. Careful examination of the visual fields will always demonstrate a scotoma of a characteristic type, and when the vision of one eye is affected by tobacco amblyopia, Dr. Traquair has never failed to demonstrate a scotoma in the other. In all but the most advanced cases the prognosis is good if the patient stops smoking and leads a healthy life, but the amblyopia may continue to become worse for a few weeks or even months before improvement begins.

MONEY FOR EDINBURGH UNIVERSITY

At the half-yearly meeting of the general council of the University of Edinburgh held last week, it was reported that in recent months bequests and gifts made to the University have amounted to £169,000. Included in this sum are a bequest by Miss Alice Leslie Inglis of not less than £25,000 for the encouragement of research and teaching in the subject of child life and health; a gift of £15,000 by Mrs. Stuart Hall for a lectureship in the pathology of diseases of children; a bequest by Miss Grace Margaret Carmichael of about £9900 for the purpose of founding scholarships for the assistance of students; and a bequest by Prof. R. Ramsay Wright, of the University of Toronto, of £3500 for the establishment of a scholarship for the encouragement of research in zoology.

The Lewis Cameron fund is to be administered as follows: £3000 for the establishment of prizes for the best papers on subjects related to bacteriology or to the diagnosis of diseases; £15,000 for the endowment of a teaching fellowship in bacteriology; £15,000 to endow one of the existing lectureships of the department of bacteriology; £10,000 to form a fund for the expenses of research work in bacteriology and the diagnosis of diseases; £10,000 for a fund to provide the medical library with books and periodicals relating to bacteriology, and to the diagnosis of diseases. The remainder of the estate will be used to form the nucleus of a medical buildings extension fund.

M.D. EXAMINATION

The clinical examination for the degree of M.D. is still divided into a major and a minor part. It is, however, no longer necessary to profess a special subject, for both these sections can be taken in clinical medicine. The major part of the examination must be taken in clinical medicine unless the special subject professed is anatomy, physiology, pathology, bacteriology, pharmacology, forensic medicine, public health or midwifery, and gynæcology.

UNITED STATES OF AMERICA

(FROM AN OCCASIONAL CORRESPONDENT)

EMERGENCY MEDICAL RELIEF

A SUFFICIENT experience of emergency medical relief under the provisions of Bulletin No. 7 Federal Emergency Relief Administration has now been obtained to justify an estimate of the success of this system of providing medical care for the indigent sick. It is at least obvious that some day a much more comprehensive plan will be needed. Neither relief administrators nor the medical profession are satisfied with the present provisions. There are two fundamental weaknesses which nobody can dispute: (1) that the distribution of the medical relief is in the hands of laymen; (2) that the funds available are totally inadequate to meet the need. The least unsatisfactory administration has been secured where local medical societies have accepted the budgetary insufficiency as an immutable fact or have taken over the responsibility of providing the administrative machinery. In these cases the doctors do a great deal of work for nothing, but as they are used to working for nothing can at least congratulate themselves on getting some subsidy, however small.

The inadequacy of funds leads to strange rulings. Thus no matter how urgent a person's need, or how completely devoid of resources, he may not be sent to a hospital at F.E.R.A. expense. Most States interpret the ruling to exclude payment of the doctor's fees if he attends a patient in a hospital.

Thus if a doctor wishes to collect a fee for appendectomy he must perform the operation on the kitchen table.

The treatment of syphilis would appear to be allowable on the ground that this disease interferes with earning capacity and also on the ground that it threatens life or health. But on the other hand it is frequently disallowed on the ground that it is a chronic disease. The Colorado relief administration has definitely ruled that "chronic conditions such as diabetes, tuberculosis, cancer, nephritis, venereal disease, epilepsy, &c., are not to be considered our responsibility." This in spite of the fact that Bulletin No. 7 does specifically provide for the treatment of chronic diseases. Furthermore, it appears to be the intention of the Federal administrator and the practice of the State administrators that no one may receive medical aid unless he is already on the list of those receiving material aid. Many a family may be able to buy enough groceries on their regular wage and still have nothing to spare when sickness visits them. These families it seems are not eligible for medical relief, even though the sickness be acute and dangerous. Your correspondent is advised that such probably would be the ruling though he has been unable to obtain any definite ruling from the Federal Emergency Relief Administration.

MEDICINE AND THE LAW

Refreshing the Memory

A LEGAL contemporary has recorded that in Smith *v.* Lowry (the claim against an osteopath summarised in this column on April 6th) a medical witness was allowed to refresh his memory as to the condition of a patient by referring to notes made by one of his pupils. Counsel on the other side objected. As it appeared that the witness had instructed the pupil to make the notes and had read the notes at the time, Mr. Justice Talbot overruled the objection.

A witness is ordinarily prevented from proving any fact by evidence of some previous statement made by himself outside the court. If, however, the statement is a written one, he can refresh his memory of facts formerly within his knowledge by looking at the document. The written statement need not have been made at the very moment of the transaction to which it relates; it is merely necessary that the note should have been made at a time when the witness's recollection of the facts was still clear and distinct. Witnesses have been allowed to refresh their memory by inspecting a note made within a week of the transaction, but not where the note was made six months afterwards. And, as in Smith *v.* Lowry, the note need not have been made in the witness's own handwriting, provided that it was made under his personal observation or was recognised by him as a correct record at a time when the facts were fresh in his mind. So the master of a ship, giving evidence of a voyage, may refresh his memory by reference to entries in the log-book made by the mate, or a tradesman may look at account-books kept by a clerk.

Expert witnesses are allowed to refresh their memory by referring to treatises which they habitually consult. This step does not make the treatise evidence in itself; the witness is obliged to give the result in his own words and on his own responsibility. In cross-examination, of course, an expert witness is often invited to refer to text-books in the hope that he will admit that he is wrong.

THE SERVICES

ROYAL NAVAL MEDICAL SERVICE

Surg. Comdrs. A. de B. Joyce, H. H. Babington, and G. H. Hayes to *President* for Medical Dept., Admiralty.

Surg. Lt.-Comdrs. E. B. Pollard to *Galatea* and to *Pembroke* for R.M. Infirmary, Deal; J. J. Keevil to *Victory* for R.N.B., Portsmouth; D. C. Drake to *Drake* for R.N. Hospital, Plymouth; and J. L. Malone to *Arethusa.*

Surg. Lts. E. James to *Milford* on recommg., and W. J. M. Sadler to *President* for course.

ROYAL NAVAL VOLUNTEER RESERVE

Surg. Lt.-Comdr. R. R. B. Roberts to *Victory.*

Surg. Lts. G. F. S. Parker to *Iron Duke*; R. D. Jenkins to *Victory*; and W. T. R. Chapman to *Durban.*

A. I. L. Maitland entered as Proby. Surg. Lt. and attached to List 1 of the Clyde Division (headquarters).

Proby. Surg. Sub-Lt. K. E. O. Ringdahl to *Renown.*

ARMY MEDICAL SERVICES

Col. H. H. J. Fawcett, D.S.O., h.p., late R.A.M.C., retires on ret. pay.

ROYAL ARMY MEDICAL CORPS

Short Service Commissions.—Lts. (on prob.) R. S. Vine, J. E. Jameson, R. H. Wheeler, and J. J. C. Rainsbury, are confirmed in their rank.

The undermentioned Capts. to be Majs. (Jan. 28th, 1935): J. N. Atkinson and J. D. Corner. (Substituted for notification in the *Gazette* of Feb. 8th, *vide* THE LANCET, Feb. 16th, 1935, p. 398.)

TERRITORIAL ARMY

Capt. F. R. Curtis resigns his commn.

Lt. W. R. Nash to be Capt.

R. W. D. Turner (late Cadet Serjt., Epsom Coll. Contgt., Jun. Div., O.T.C.) to be Lt.

H. W. E. Jones to be Lt.

B. L. McQuillan (late Offr. Cadet, Queen's Univ. Contgt., Belfast, Sen. Div., O.T.C.) to be Lt.

The Efficiency Decoration has been conferred upon Col. A. H. Gosse, Hon. Col. F. Marsh (R.A.M.C. units, 48th (S. Midland) Div.) (Bt. Col. ret. T.F.), and Lt.-Col. and Bt. Col. H. L. Garson.

TERRITORIAL ARMY RESERVE OF OFFICERS

Capt. G. McLoughlin, from Active List, to be Capt.

ROYAL AIR FORCE

Flight Lts. R. E. Alderson to Central Medical Establishment, London., and R. E. W. Fisher, to Aircraft Depôt, Karachi, India.

INDIAN MEDICAL SERVICE

To be Capt. (on prob.): E. C. Hicks.

To be Lts. (on prob.): I. J. Franklen-Evans, J. Duffy, A. W. Sampey, J. Reidy, G. C. Welply, C. L. Greening, C. B. Jones, K. Cunningham, G. F. Adye-Curran (secd.), and J. F. A. Forster (secd.).

DEATHS IN THE SERVICES

Squadron Leader ROBERT BOOG WATSON, who died after a short illness at the West London Hospital on May 2nd, was born in Edinburgh on Christmas Day, 1893, the younger son of Charles V. Boog Watson, an engineer. He was educated at Merchiston School and in France and Germany, but owing to an accident in which he lost a foot he was unable to serve during the late war. He graduated M.B., Ch.B. Edin. in 1919, was house physician to Sir Robert Philip, and then house surgeon at the Royal Infirmary. He joined the medical branch of the Royal Air Force in June, 1920, took the D.P.H. in 1921, and was promoted squadron leader in June, 1930. He served twice in Iraq, and at the time of his death was assistant director (hygiene) at the Air Ministry. His early death is much to be regretted; he was a loyal and zealous officer of a type which can ill be spared. He leaves a widow and one daughter, with whom much sympathy is felt.

PUBLIC HEALTH

RESERVOIRS OF BOVINE TUBERCLE BACILLI: THEIR RELATION TO A SAFE MILK-SUPPLY

BY R. H. PARRY, M.D., M.R.C.P.
MEDICAL OFFICER OF HEALTH FOR THE CITY OF BRISTOL; PROFESSOR OF PREVENTIVE MEDICINE IN THE UNIVERSITY; AND

I. WALKER HALL, M.D.
DIRECTOR OF PREVENTIVE MEDICINE LABORATORIES AND EMERITUS PROFESSOR IN THE UNIVERSITY OF BRISTOL

ALTHOUGH the attainment of tubercle-free herds may appear to some to be a visionary hope, it must be admitted that there is cause for immediate dissatisfaction that the animal returns of laboratories do not point to a falling curve similar to that of human tuberculosis. The administration of the milk and dairies order and the tuberculosis sub-order by local authorities have not resulted in any tangible reduction in the output of tuberculous milk. The problem was, perhaps, too great to be tackled by local authorities on such lines. It is not surprising, therefore, that health authorities are turning to pasteurisation as a means of protecting the public from all the associated risks. Nevertheless, we should not thereby be diverted from the aim to free our herds from tubercle, or at all events, to make greater strides to that end.

While it is customary to express the milk tubercle problem in terms of varying numbers of infected cows or in percentages of tuberculous milks, there is another angle from which the question may be considered, namely, the numbers of infected farms that act as reservoirs for the dissemination of bovine strains.

For instance, during 1934 we found that 5·1 per cent. of 485 samples of milk from one area contained virulent tubercle bacilli. This conjured up the vision of some 23 cows with tuberculous udders. But when the sources of the milk were more closely scrutinised, it was evident that these animals were limited to 14 farms and that the milk therefrom was intermittently tuberculous over several months. Hence it was incumbent to envisage these sources as continuous, or recurrent foci, for the spread of tubercle bacilli via milk, utensils, workers, calves, and other animals in the same farm. In some definite instances it was possible to trace the infection by transfer of the cows to adjacent farms and markets. The potentialities for infection from each of the 14 centres assumed greater proportions than could be dealt with except by measures more systematic than those that to-day are considered to be satisfactory.

DELAY INVOLVED IN PRESENT PROCEDURE

What, in fact, are the actual procedures that at present may follow a report from a consuming centre that bulk milk from a specified source has been proved to contain virulent tubercle bacilli?

The county officials visit the herds concerned, examine the cows individually, condemn what they can upon inspection, and then probably take a few selected samples of milk for laboratory examination. By this means the infection may be cleared, but it is interesting to note how often clinical examination fails to reveal the source of infection even though there is evidence of the definite existence of such a source. Anyhow, the method as a whole usually takes many weeks for completion and during this time the milk remains infected. A few instances may be cited to demonstrate the existence and persistence of these bacillary reservoirs.

Farm A

Dec.	Bulk samples contain tubercle bacilli.
Jan.	Clinical examination of 11 cows. All healthy.
Feb.	Herd divided into groups. Two groups of 3 and 4 cows yield T.B. milk.
Mar.	Two of above 7 had gone dry. Of the other 5, one yielded T.B. milk.

Farm B

June.	Bulk milk from 45 cows contained T.B.
July.	Vet. selected 7 cows for sampling. One milk yielded T.B.
Aug.	Bulk samples yielded T.B. All cows grouped. One group = T.B. milk. Two cows of group found to give T.B. milk.

Farm C

April.	Bulk milk = T.B.
May.	Vet. took sample from selected cow = negative.
Aug.	Bulk milk = T.B.
Sept.	Herd sampled in groups. One cow gave T.B. milk.
Oct.	Herd sold by auction before definite clearing samples could be taken.

Farm D

April.	Bulk milk = T.B. ÷. Vet. selected 4 samples. All were negative.
July.	Bulk milk = T.B. ÷. Vet. selected 4 samples. All were negative.
Sept.	Bulk milk still tuberculous.

Farm E

July.	Bulk milk	= T.B. ÷.
Aug.	,, ,,	= T.B. ÷.
Sept.	,, ,,	= T.B. not found.
Oct.	,, ,,	= T.B. ÷.
Nov.	,, ,,	= T.B. not found.
Dec.	,, ,,	= T.B. ÷.

These results may be summarised thus:

Length of time tuberculous milk was supplied before clearance

Farm A	4 months.	Farm D	6† months.
,, B	3 ,,	,, E	6† ,,
,, C	6* ,,		

* Herd distributed before clearance.
† Still tuberculous.

These records may suffice to support a contention that a more comprehensive and combined attack is necessary for the effective eradication of rural foci of tuberculous material. For many months these herds were excreting tubercle bacilli intermittently, or tuberculous animals were being introduced into the herd at frequent intervals, and the infected milk was being distributed. At once, however, when alterations in procedure are suggested, questions of finance introduce apparent difficulties. These, in this matter, are the children of the myopic economist. It is easy to understand the restricting hand of county and civic authorities, for the problem is essentially national. It is less easy to appreciate the lack of prominence attached to the point that, while the producer suffers a small loss when a tuberculous animal is destroyed, this loss is as nothing to the retention of a tuberculous cow in an otherwise healthy herd. The inevitable spread of tubercle bacilli gradually reduces the value of each of the others, and the frankly tuberculous one soon becomes the price of skin and bone. It is not perhaps within the scope of this article to discuss the part played by compensation in this matter. Can the lot of the dairy farmer be classed among the speculation trades, wherein good margins of profit compensate for heavy risks? If not, compensation on a liberal scale must be considered. Surely we have progressed sufficiently to-day to be convinced that the supply of fresh, clean, safe milk at a reasonable cost is a national need to be met by national provision. At all events, it is clearly evident that the present-day methods are inadequate and uneconomical.

SUGGESTED LINES OF ACTION

Apart from the wastage of hardly won food and the costs of damaged health, the score of economy alone is an urge towards the limitation of a persisting spread of tubercle bacilli from known sources of infection. It is permissible therefore to suggest some lines of action that might lead to more effective protection of the industry and community.

1. That when a milk-supply is proved to be tuberculous, neither removal from nor access of animals to that herd should be allowed without a certificate from the district veterinary official.
2. That at the outset of inspection, the milk from each member of the herd should be sampled. That there should be a close coöperation, consultative and operative, between the veterinary officials and available laboratories, in order to determine what further inspections and samplings are necessary.
3. That until the joint examinations indicate the absence of tuberculosis in the herd all the milk produced should be compulsorily pasteurised.
4. That during this period of probation all calves should be carefully supervised and protected. That efficient cleansing and disinfecting of the premises should be carried out at prescribed intervals and that the manure should be treated so as to destroy pathogenic organisms.

While these suggestions may appear more cumbersome on the one hand, and less radical on the other, than tuberculin testing, yet their application should be less disturbing to economic conditions and so meet an objection that is frequently advanced against routine tuberculin reactions.

We have not attempted here to deal with the problems associated with the tracing of infected milks to their particular source. Bulk sampling is a practical proposition in Bristol. It is not so in large cities where milk has been transported in glass-lined tanks containing as much as 3000 gallons of milk, a procedure that aggravates the situation in regard to the dissemination of disease.

It would have been a passing achievement if we could have pointed to the effective clearance of 14 reservoirs of infection in one area. Such it seems is not a possibility under existing conditions. Perhaps, however, our citation of these records may induce other centres to review their own from a similar standpoint. If their observations confirm our findings, they would constitute a tacit submission for an early reconsideration of existing procedures. At the same time they would bring before all those associated with its production the necessity of convincing the consumer that they are unwearying in their aims to provide a consistently safe and clean milk. The success of "milk campaigns" depends largely on such a satisfaction. But in any case one of the essential features of an extended programme for betterment should be an active coöperation between field and laboratory and the arming of both with sufficiently effective financial and controlling powers.

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDED APRIL 27TH, 1935

Notifications.—The following cases of infectious disease were notified during the week: Small-pox, 0; scarlet fever, 1994; diphtheria, 996; enteric fever, 16; acute pneumonia (primary or influenzal), 1445; puerperal fever, 47; puerperal pyrexia, 124; cerebro-spinal fever, 23; acute poliomyelitis, 1; encephalitis lethargica, 9; dysentery, 7; ophthalmia neonatorum, 84. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the London County Council on May 4th was 3459, which included: Scarlet fever, 1035; diphther [illegible] whooping-cough, 365; puerperal feve [illegible] encephalitis lethargica, 269; [illegible] Hospital there were 18 babies [illegible] neonatorum.

Deaths.—In 121 great towns, including London, there was no death from small-pox, 2 (0) from enteric fever, 25 (0) from measles, 5 (0) from scarlet fever, 36 (4) from whooping-cough, 32 (10) from diphtheria, 51 (13) from diarrhœa and enteritis under two years, and 137 (15) from influenza. The figures in parentheses are for London itself.

There is a sharp fall in the number of influenzal deaths which are now chiefly concentrated in the northern area. This week deaths were reported from 52 [illegible] orting 22, Leeds 16, Middlesbrough [illegible] town more than 3. Hastings and [illegible] fatal case of enteric fever. Six deaths from measles occurred at Wigan, 5 at Birmingham. Whooping-cough was credited with 5 deaths at Middlesbrough. In no great town were more than 2 fatal cases of diphtheria reported.

The number of stillbirths notified during the week was 290 (corresponding to a rate of 42 per 1000 total births), including 53 in London.

PANEL AND CONTRACT PRACTICE

Unemployment and Medical Benefit

THE most difficult problem in national health insurance at the present time is the effect of unemployment on the scheme. The reduction of income and the increased expenditure on benefits, whether direct or indirect, form a vicious circle which ever since the first attack of post-war depression which began in 1920 has required palliative treatment in the shape of a series of Prolongation of Insurance Acts. In 1928 an attempt was made to put the matter on a permanent basis, but it was soon apparent that the attempt had not solved the problem, and after further Prolongation Acts in 1930 and 1931, the new Act of 1932 dealt with the situation up to the end of 1935 by prolongation of insurance and partial excusal of arrears. Insurance practitioners, particularly those in the depressed areas, have already appreciated some of the effects of this Act in respect of those unemployed insured persons whose title to medical benefit ceased after Dec. 31st, 1933. But an even more serious situation is due to arise at the end of this year when these people expect to lose their contributory pension rights as well. The health and pensions provisions of our scheme of social insurance are so interlocked that it is not always appreciated that there is an essential difference between them. Broadly speaking, the health provisions may be likened to fire insurance where the risk is a potential day-to-day risk, but pensions are more akin to an endowment assurance where the contributions or premiums are to provide for a future claim at age 65, or in respect of the contributor's widow or orphan.

The National Conference of Friendly Societies have had under consideration a scheme for continuing medical benefit to unemployed persons who have been insured for ten years and have paid not less than 400 contributions, so long as they can prove their availability for, but inability to obtain, insurable employment, and the beneficiaries under the scheme would thereby retain their title to pension rights and to certain health insurance benefits. The proposal is that the charge in respect of medical benefit against insurance funds should be a collective responsibility of the National Health Insurance

Fund as a whole and that, in allocating this cost against the approved societies, no regard should be had to the financial positions of the various societies. The foregoing scheme has, however, been adversely criticised, as it is thought not to go to the root of the matter. Various groups of approved societies have given intensive consideration to the question, and it would appear that there is now a certain degree of agreement that arrears might be disposed of by a charge on each society's contribution income, each society in its turn to receive back out of the fund thus created its own measure of relief calculated upon the extent of unemployment amongst its members. This plan would make the unemployment risk a common charge on all types of societies which would vary as the unemployment figures varied. It has been stated that the charge at the present time would represent substantially less than one penny per contribution actually received by societies.

But the scheme, statesmanlike though it is, may have an adverse effect upon additional benefits, dental, ophthalmic, and the like, and so it is not surprising that some voices are already asking as to the possibility of securing a Government grant. This is, however, a matter of politics on which the medical profession as such has no voice, although they may observe with gratification that attempts are being made to preserve not only medical benefit but the other benefits of health and pensions insurance for those who have fallen on hard times owing to continued unemployment. Two groups of societies have recently expressed their readiness to join in providing substantial financial assistance to the 5,000,000 insured persons who are in arrear, due to unemployment, in order that their right to statutory benefits, medical and other, may not be jeopardised.

Supply of Anti-diphtheria Remedies

Some months ago a medical service subcommittee dealt with a case in which an insurance practitioner treated a young dressmaker as a private patient and rendered an account for £6 7*s*. 6*d*. for the period Oct. 30th to Nov. 2nd, but of this amount £4 19*s*. 6*d*. represented his charge for diphtheria antitoxin. There was a conflict of testimony as to when the practitioner was first asked to treat the girl as an insured person. At the hearing the practitioner, who was under the impression that his secretary had paid the local authority for the antitoxin, expressed his willingness to withdraw the account. It was it seems the practice of the local authority in question to supply the antitoxin gratuitously for use in necessitous cases. Under Clause 9 (8) of the Terms of Service a practitioner is required to supply to a patient such drugs and appliances as are required for immediate administration or application, and he may supply any other drug which is administered by him in person. But reference to the appendix to the distribution scheme will show that serums can be paid for only when supplied to patients for whom a supply is not made gratuitously available by any public authority. So far as diphtheria antitoxin is concerned the reason for the proviso is that the Diphtheria Antitoxin Order of August 15th, 1910, is not mandatory but discretionary, and it is for the local authority to decide whether a supply of diphtheria antitoxin shall be made gratuitously available, and to interpret the term "poorer inhabitants." Some authorities supply antitoxin gratuitously to all persons requiring it.

An inquiry was recently addressed to the Ministry of Health as to whether diphtheria prophylactic and the material for the Schick test may be regarded as drugs when required in connexion with the immunisation of insured persons. The reply was that while the Minister has no authority to give a ruling—the question can be authoritatively decided only in the manner furnished by the regulations—he is of opinion :—

(*a*) That diphtheria prophylactic is a drug, the cost of which would form a proper charge on the chemists' fund when ordered on the official prescription form in respect of a "prescribing" patient.

(*b*) That preparations which are used for application to the human body for diagnostic purposes must be regarded as properly chargeable to the chemists' fund in the case of "prescribing" patients or the practitioners' drugs account in the case of "dispensing" patients.

An Uncommon Representation

Under Article 44 of the Medical Benefit Regulations the local medical or panel committee have power to consider any complaint made to them by one insurance practitioner against another involving the efficiency of the medical service, and the committee may make representations to the Minister that the continuance on the medical list of the practitioner against whom complaint is made would be prejudicial to the service. The power thus conferred is very seldom exercised to the extent of suggesting the removal of a practitioner's name. Quite recently Dr. A made complaint that an insured person on his list had been transferred to Dr. B's list without the patient's knowledge or consent. The patient's wife was being attended by Dr. B, who on her second visit to him asked her to produce her husband's medical card the next time she called. It seems that he kept the card and told the woman that when she received the card back with a transfer form attached she should take the medical card again to him. According to her own statement the woman followed these instructions and some time afterwards when in hospital her husband came to visit her, bringing with him a new medical card with the name of Dr. B on it. Dr. B admitted that the letter to the insurance committee applying for consent to transfer at the end of the quarter, which purported to be from the insured person, was written and signed by his housekeeper upon his instructions. He had never seen the insured person, but took the action he did at the wish of the patient's wife. The subcommittee were not disposed to accept his assertion that the wife was anxious for the transfer, and passed a resolution expressing their opinion that his continuance on the medical list would be prejudicial to the efficiency of the medical service of insured persons. The Minister will now appoint a day for the holding of an inquiry. Whatever may be the outcome of this particular case, it is evidently most undesirable for a practitioner to act as the agent of an insured person in the matter of applying for consents to transfer. Practitioners accepting transfers should insist that the application on the medical card or on Part A 1 (the red printed slip) should be fully completed and signed by the insured person concerned. It should be added that it is 13 years since such an inquiry was held at the instance of the London panel committee.

BIRKENHEAD GENERAL HOSPITAL.—During the last eight years no beds have been added to this hospital and the wards are crowded. The pressure is greatest in the women's wards, and many patients are waiting for admission. A few rooms are set aside for paying patients, but the demand has grown from 15 in 1926 to 166 last year, and more provision must be made for such cases.

OBITUARY

JAMES PRAIN STURROCK, M.D. Edin.

THE death occurred on April 24th, at Inverness, of Dr. James Prain Sturrock, a commissioner of the General Board of Control of Scotland. Already a graduate in arts at the university of St. Andrews before turning to medicine, he received his medical education in Edinburgh, graduating as M.B., C.M. in 1897. Ten years later he proceeded to the M.D. degree, which he obtained with honours. The whole of his professional life was spent in institutional or official connexion with the treatment of mental disease. First appointed as senior assistant medical officer in the Stirling District Asylum at Larbert, he became assistant medical officer at the Midlothian and Peebles Asylum and later medical officer to the Perth Prison and State Inebriate Reformatory, being also superintendent of the criminal lunatic department. He was appointed a deputy commissioner of the General Board of Scotland in 1914, and became in 1922 full commissioner. His literary output was considerable and useful, dealing with the relations of mentality to crime, with the influence of inebriety upon those relations, and especially the connexion between feeblemindedness and inebriety. He published in the *Journal of Mental Science*, 1910, arising out of his experiences at Perth, a paper on certain insane conditions to be found among the criminal classes. He wrote on the modern aspects of eugenics in the transactions of the Perth Natural Science Society and followed that with an essay on inebriety and feeblemindedness in the *British Journal of Inebriety* for 1912. These essays were characterised by their practical directions, and were founded upon much and close personal observation.

Dr. Sturrock, whose death occurred suddenly from cerebral hæmorrhage, while conducting an official inspection, leaves a wife and daughter.

DR. AXEL REYN

LATE DIRECTOR OF THE FINSEN LIGHT INSTITUTE, COPENHAGEN

Dr. Axel Reyn, who died at the age of 63 on April 22nd, was, through his work in connexion with, and as successor to, the late Prof. Niels Finsen, widely known in the medical world. He became associated with Finsen in 1897 and was later appointed chief of the dermatological department of the Finsen Institute. He made a well-deserved reputation as a dermatologist and will be remembered for his work in actinotherapy in relation to tuberculosis and especially in the local and general treatment of lupus vulgaris. His knowledge of this disease was profound and his skill in its treatment was widely recognised. Sufferers from lupus flocked to the Finsen Light Institute from all parts of the world, and many will ever have reason to recall with gratitude the success with which they were treated. He devised the Finsen-Reyn lamp, a modification of the original Finsen lamp, which is especially useful for the treatment of individual cases, and has been introduced into hospitals and clinics the world over, where it is still successfully employed. He introduced carbon arc baths for the general light treatment of surgical tuberculosis, and with N. P. Ernst published his method in 1914. In 1913 he published "Die Finsenbehandlung," an important work wherein was collected all existing available knowledge of light therapy, and he wrote numerous valuable papers dealing with lupus vulgaris, and the treatment of X ray burns and ulcers, and of tuberculosis of the glands. Honours came to him plentifully, and he was elected honorary member of many learned societies both in Denmark and abroad. Perhaps the honour he most greatly appreciated was his election as President of the International Light Congress held in Copenhagen in 1932 where glowing and well-merited tributes were paid him by colleagues from many countries, and a special number of *Strahlentherapie* was published in his honour. But already the disease, tuberculosis, which eventually killed him, had attacked him severely, and he resigned the directorship of the Finsen Institute in 1933, being elected president of the board. His successor at the Institute is Dr. Sven Lomholt.

Sir Henry Gauvain, to whom and to Dr. A. E. Kissmeyer, Reyn's friend and colleague, we are indebted for much of this information, writes: "For those who were privileged to know him the death of Axel Reyn creates a great sense of personal loss. His was a modest, lovable personality, generous, always ready to help colleagues, and devoted to the interests of his patients. He was a man of deep culture and wide interests, fond of travelling and particularly of the Mediterranean coast. Of recent years he was in the habit of spending the spring on the Riviera and this year had only returned to Copenhagen three weeks before his death. He married in 1893 Elizabeth Finsen, sister of Niels Finsen; she survives him, but they had no children. Reyn was particularly interested in the promotion of preventive measures against tuberculosis and debilitating diseases in children, and the success which attended his efforts in these directions proves the necessity of their application."

THE LATE GORDON ERNEST ODDIN-TAYLOR, M.R.C.S. Eng.—A South African correspondent sends the following notes upon the career of Dr. Oddin-Taylor, who died recently in Pietermaritzburg, where he was senior surgeon to Grey's Hospital at the time of his death, which followed a serious operation. "Dr. Oddin-Taylor was a member of a well-known Norfolk family and received his medical education at St. Thomas's Hospital, where he qualified with the English double diploma in 1896. He went out to join relatives who were practising in Pietermaritzburg, and for 30 years practised in that town. He was appointed surgeon to Grey's Hospital in 1907, thus serving the institution for the exceptionally long period of 28 years. He had been a member of the old Natal Medical Council and for a long period represented the Natal Inland Branch on the Federal Council. He was held in high esteem by the medical and nursing profession for his skill as a surgeon, and was certainly one of the best known figures in the Natal capital."

MIDDLESEX HOSPITAL.—The Duke of Northumberland has been elected president of this hospital, an office that since the first few years of the hospital's existence has been held by the head of the house of Percy. On the death of the last president the present duke was still a minor, but he has now agreed to continue the tradition of close on 200 years.

HOSPITAL FINANCE AT TAUNTON.—There are now 18,566 contributors to the Taunton and Somerset hospital week's committee scheme, over a thousand more than last year, and the total receipts for the year amount to over £10,000.

infectious diseases by the bacterial toxins I induced artificially by intramuscular injections of milk (5–10 c.cm.) or of bacterial proteins such as Omnadin or Stormin (Austrian Serum Works). This immunising stimulus, combined with the osmotic stimulus of the dextrose proved sufficient to abort the attack in about 70 per cent. of the cases of lobar pneumonia, typhoid, erysipelas, and Bang's fever. Whenever possible we administer early in pneumonia and before the fifteenth day in typhoid a dose of albumin intramuscularly, and 20 hours later 20 c.cm. of 50 per cent. dextrose solution with 0·25 mg. strych. nitr. intravenously. In pneumonia fever and pain disappear by the fourth or fifth day after the beginning of this treatment. In typhoid the swelling of the spleen and the abdominal symptoms yield as a rule within four days, the patient becoming afebrile by the sixth day. I have published temperature curves of such cases (Wien. med. Woch., 1931, lxxxi., 254) and Dr. Reinthaller has recently recorded his observations on 160 cases of pneumonia at the St. Pöltner Hospital (Ars Medici, 1934, p. 512). He confirms the quick and sometimes astonishing effect. Pneumonia of the epidemic kind commonly known as influenza (Grippe) reacts less or not at all. Of 90 typhoid cases in my private practice and in hospital I lost only two, one from hyperpyrexia (? after insolation), the other after operation for a wrongly supposed perforation. In the longer cases it was necessary to inject osmon two or three times. Since there is no actual shock this treatment can be carried out at the patient's home if nursing is available.

I am, Sir, yours faithfully,

KARL STEJSKAL.

Spital der Barmherzigen Brüder, Vienna, May 3rd.

NASAL RECONSTRUCTION: THE TUBED PEDICLE FLAP

To the Editor of THE LANCET

SIR,—In reply to Dr. Aymard, I have nothing to add to what you published in the correspondence columns of THE LANCET in August, 1920, in reply to a similar claim by him; *except* to draw his attention to my recent publication re the tubed pedicle in *Surgery, Gynæcology and Obstetrics* in which priority of publication of this flap is given to Filatoff. With regard to the stirrup flap mentioned by Dr. Aymard, I would refer him to Tripier's operation published in the *Revue de Chirurgie*, No. 4, 1890.

I am, Sir, yours faithfully,

Harley-street, W., May 3rd. H. D. GILLIES.

MATERNAL MORTALITY

To the Editor of THE LANCET

SIR,—Mr. Eardley Holland's address to the Royal Sanitary Institute published in your issue of April 27th is most valuable. It is a long time since—in the middle 'seventies—I studied midwifery in Edinburgh under Matthews Duncan who impressed upon us that "festina lente" was to be our guiding motto when attending an expectant mother. For more than 30 years I had a country practice with an average of one confinement a week, 50 miles away from a hospital, and not within easy reach of a medical friend. For some years there were no nurses—only friendly neighbours too eager to be of help, who never learned to understand why I wished my patient not to bear down in the early stage. In tedious cases I was often urged by relatives to use instruments and bring the delivery to an end. This I always resisted, and I gave no chloroform until the second stage was well advanced, stating that if given earlier the pains were weakened and the labour prolonged. There was often great difficulty in making the patient and friends believe this. In using forceps I felt I was acting more safely if my patient was fully conscious, for she would easily show when they hurt her, however gently they were applied. After they were in position she got more chloroform, though in very small amounts. I am therefore in accord with Mr. Eardley Holland on all these points. Nature does the work best, and is much to be preferred to instrumental aid with its risk of injuries to the soft parts. In a busy practice one is often tempted to bring the case to an end, but the question should always be what is best for the patient.

I am, Sir, yours faithfully,

Harrogate, May 6th. JAMES G. MACASKIE.

SUPPLEMENTS TO THE DIET OF CHILDREN

To the Editor of THE LANCET

SIR,—The report recently published by Mr. T. W. Simpson and Mr. Eric C. Wood on the value of supplements to the ordinary mixed diet of children, which is annotated in THE LANCET, May 4th, shows clearly that such mixed diet is deficient at any rate in those factors which make for increased growth. The authors' other conclusions cannot however be accepted without criticism. In the first place, they use as a criterion the weight increase *during* the six weeks during which each supplement is being given. Since growth-factors, whatever their chemical nature, continue to exert their influence for varying periods after they are withdrawn from the diet, it is doubtful if the precaution of giving the different diets in rotation for periods as short as six weeks balances this error. A state of nutrition, as Dr. Magee has recently emphasised, is dynamic, not static, and sufficient time must be allowed for each factor to exert its influence after the effects of the previous one have worn off.

In the second place, the authors conclude that because a "calorie" supplement (vitamin content unstated and unknown) produced better growth than either cod-liver oil or halibut-liver oil and milk, that "balanced calories" are of greater benefit to the child than "vitamins." Since two of the supplements supplied only vitamins A and D, and the third, containing malt, egg, and lemon juice, presumably contained small quantities of the B complex and C in addition, such a sweeping conclusion scarcely seems justified. Vitamins do not fall into a chemical group, and it is as unreasonable to speak of "vitamins" meaning A and D as, for example, of "minerals" meaning only calcium and phosphorus and disregarding iron.

The impression cannot be avoided that different results might have been obtained had the growth factors of the B complex been considered in addition to vitamins A and D.

I am, Sir, yours faithfully,

Wembley Park, Middlesex, May 7th. M. D. WRIGHT.

PUTNEY HOSPITAL.—Princess Arthur of Connaught visited this hospital last week and opened the new nurses' home. Extensions at the hospital have cost £30,000, and there is still a debt of £8000.

OSWESTRY COTTAGE HOSPITAL.—A new cottage hospital is required at Oswestry, and a scheme has been launched for building it at a cost of £20,000. An effort is being made to raise a 10,000 shilling fund.

PARLIAMENTARY INTELLIGENCE

NOTES ON CURRENT TOPICS

Osteopaths Bill: Select Committee's Report

The meeting of the Select Committee of the House of Lords on the Registration and Regulation of Osteopaths Bill, which had been arranged for Thursday, May 11th, has been postponed sine die on account of the illness of the chairman, Lord Amulree. The Committee will meet again at a later date to consider their report.

Ribbon Development

In the House of Lords on Tuesday, May 7th, the Marquess of Londonderry introduced the Restriction on Ribbon Development Bill. The object of the Bill is to provide for the imposition of restrictions upon ribbon development along frontages to roads; to enable highway authorities to acquire land for the construction and improvement of roads; to preserve the amenities or control development in the neighbourhood of roads; to extend the powers of local authorities as to the provision of accommodation for the parking of vehicles and as to the prevention of interference with traffic; and for purposes connected with the matters aforesaid.

The Bill was read a first time.

HOUSE OF COMMONS

WEDNESDAY, MAY 1ST

The New Driving Test

Mr. Parkinson asked the Minister of Transport the number of persons, male and female, that had been examined for the new driving test; and the number that had failed to satisfy the examiners.—Mr. Hore-Belisha replied: Up to and including April 27th, 22,539 persons have been examined, of whom 1863 have failed to satisfy the examiners. The periodical returns furnished by the examiners do not distinguish between male and female applicants.

Mr. West: Do these figures convince the Minister that there must be an enormous proportion of motorists to-day who are unfit to drive?

Mr. Hore Belisha: It is the purpose of the test to prevent, at any rate to some degree, bad drivers from getting on to the roads.

Mr. Tinker: Have those who fail another opportunity to undergo a test?

Mr. Hore-Belisha: Yes, they can certainly submit themselves for a test again after the lapse of the statutory period.

Hospitals and Road Casualties

Mr. Leonard asked the Minister of Transport the total cost incurred by hospitals in Great Britain in treating road casualties; the amount claimed from his department by these institutions; and the total paid.—Mr. Hore-Belisha replied: According to a statement in "The Hospitals Year Book, 1935," 25,000 victims of road accidents were treated last year in the voluntary hospitals of Great Britain and Ireland at a cost of £235,000, of which £110,000 was recovered, including £80,000 under the provisions of the Road Traffic Acts and the common law. Payments to hospitals in respect of the cost of such treatment, although they may be made in pursuance of the Road Traffic Act, are not made from funds under my control.

National Health Insurance Funds

Mr. Gordon Macdonald asked the Minister of Health the total amount of the National Health Insurance funds at Dec. 31st, 1934.—Mr. Shakespeare (Parliamentary Secretary to the Ministry of Health) replied: The amount was approximately £129,500,000.

Mr. Macdonald: Does the Minister not consider it advisable that some of this amount should be used to safeguard the interests of those who are suffering from the effects of prolonged unemployment?

Mr. Shakespeare: The whole question of unemployment in relation to health insurance is being considered now.

Mr. T. Smith: Can the Minister say when the promised amending Bill will be introduced?

Mr. Shakespeare: As soon as possible.

Miners' Baths and Welfare Institutes

Mr. Lunn asked the Minister of Labour if a caretaker of a miners' welfare institute or miners' baths was treated as entitled to unemployment insurance benefit in case of unemployment; and whether such cases had been considered by the statutory committee and a recommendation made thereon.—Mr. R. S. Hudson (Parliamentary Secretary to the Ministry of Labour) replied: Broadly speaking, persons engaged in looking after miners' welfare institutes or miners' baths are regarded, in accordance with judgments given by the High Court, as being employed in domestic service and, therefore, not insurable where they are not employed in a business carried on for the purposes of gain. Both these employments, however, are among those with regard to which inquiries are proceeding with a view to the submission of a draft regulation to the Statutory Committee under Section 2 of last year's Act for the inclusion within the scope of the scheme of certain workers now excepted.

Rural Telephones in Scotland

Sir Archibald Sinclair asked the Postmaster-General in how many cases in the last three years guarantees had been demanded by the Post Office as a condition of extending the telephone in rural districts in Scotland; what was the total amount of such guarantees; in how many cases recourse had been had to the guarantors to make up any deficiency on the cost of the service; and what was the total amount of money paid to the General Post Office in respect of these guarantees.—Sir Kingsley Wood replied: During the past three years guarantees have been required in Scotland in 27 cases, all in connexion with the provision of telephone call offices in rural districts. The total amount guaranteed is £594 10*s.* a year. Nine of the call offices have not yet been in service for a year; but it has been necessary to make demands upon the guarantors in respect of all but one of the remaining 18. These demands number 29 in the period stated; and the total amount paid or awaiting payment is £568 14*s.* 10*d.* As a result of the concession which I announced on April 29th concerning the provision of additional telephone facilities in rural districts, the guarantees in nearly half these cases will be cancelled as from May 1st.

THURSDAY, MAY 2ND

Lifts and Factory Act Control

Mr. Rhys Davies asked the Home Secretary if he had considered the question of bringing lifts at residential and office premises under the Factory Acts.—Captain Crookshank (Under-Secretary, Home Office) replied: This suggestion has not been overlooked, but my right hon. friend is not in a position at present to come to any conclusion.

New Water-supply Schemes

Mr. Levy asked the Minister of Health how much of the Treasury provision for grants in aid of water-supply schemes had been expended; and what was the total expenditure on new water-supply schemes since this provision was made.—Sir Hilton Young replied: The amount of grant provisionally allocated is now £528,000 in respect of schemes of a total capital cost of £3,320,000. It is not possible to state the total expenditure on water-supply schemes since the Act providing the grant was passed in March, 1934, but during this period the loans for such schemes sanctioned by me or by Parliament in local Acts amount to £4,370,000, including £1,400,000 for rural water schemes.

Mr. Levy: In view of the warning already given by water undertakers, including the Metropolitan Water Board, as to the water shortage this summer, is the right hon. gentleman really satisfied that he is doing all that can be done to alleviate a water shortage and its consequences ?

Sir Hilton Young : My reply to that question is a suggestion that there is no apprehension of a water shortage this summer.

Expenditure on Social Services

Mr. West asked the Chancellor of the Exchequer the total net expenditure in 1934 on social services, excepting sums spent on war pensions.—Mr. Chamberlain replied : I am afraid that the information asked for is not yet available. As the hon. Member is no doubt aware, full details of expenditure on social services are given in the Return of Public Social Services published each year. The latest issue of the Return (Command Paper 4749 of 1934) contains the figures for 1933, and those for 1934 will be included in the next issue which will be published in the autumn.

Mr. West : Is it not a monstrous thing that the figure of £500,000,000, so often quoted in this House, is grossly misleading, and is it not the fact that the increase in social services during the last few years has been largely offset by the increasing taxation borne by the people indirectly ?

Mr. Chamberlain : I cannot answer that question without notice.

Lieut.-Commander Agnew : Is it not a fact that we spend each year more than any country in the world on social services and that we get the best results ?

Mr. G. Griffiths : Is it not the fact that there is more stopped out of the wages of the working-class in this country than is the case in any other country ?

No further answers were given.

Hospitals and Milk-supplies

Mr. Leonard asked the Minister of Agriculture if his attention had been called to the fact that, owing to the regulations of the Milk Marketing Boards, some hospitals had had the price of milk raised against them from 33 per cent. to 63 per cent. ; and to what extent the matter was being considered, so as to assure no limitation of milk consumption in such institutions and no substitution of inferior grades.

Sir John Haslam asked the Minister of Agriculture what was the reason why hospitals could not purchase the milk they required for their own use at about the same wholesale price as they did before the existence of the Milk Marketing Board.—Mr. Elliot replied : As regards the prices payable by hospitals for milk supplied under the Scottish Milk Marketing Scheme, 1933, which were considered by the Committee of Investigation for Scotland, I would refer Mr. Leonard to the reply given on April 8th by the Secretary of State for Scotland. The position in England and Wales is that the Milk Marketing Board have prescribed a form of contract under which hospitals contracting with producers can obtain supplies at the wholesale price with small additional premiums for level deliveries or other special services. Hospitals not contracting with producers may obtain supplies from wholesalers under the resale clauses of the ordinary contract at the wholesale price plus premiums varying from ½*d.* per gallon for large quantities to 1½*d.* per gallon for small quantities. From particulars furnished by the British Hospitals Association, it appears that as regards approximately two-thirds of the voluntary hospitals in England and Wales the price paid for milk during 1934 was, on the average, about 15 per cent. more than in the year preceding the scheme, but that in individual cases the increase was 33 per cent. and in one instance 63 per cent. I understand that the Association have discussed the matter with the Milk Marketing Board, and that after very careful consideration the Board have not been able to see their way to authorise the sale of milk to hospitals at less than the rates laid down, but they have suggested that if the Association can obtain the concurrence of the Central Milk Distributive Committee (as representing the distributive trade) to the supply at net wholesale prices they will give sympathetic consideration to a variation of the terms of sale accordingly.

Sir John Haslam asked the Minister of Agriculture, if, in view of the indignation that existed amongst hospital authorities at the high prices they had to pay for their milk-supplies compared with the low prices paid by chocolate and cheese makers, he would take steps to obviate this differentiation.—Mr. Elliot replied : My hon. friend will appreciate that the effect of replacing purchases of milk at liquid rates by purchases at the manufacturing prices is to increase the loss already occasioned to milk producers by reason of these prices. I am not quite sure what steps my hon. friend has in mind to meet this difficulty, but I should be glad to consider any proposals he suggests.

Venereal Diseases

Sir Arnold Wilson asked the Minister of Health whether his attention had been drawn to the fact that the death-rate from syphilis for 1933 was higher than for 1924, and the total number of reported new cases of venereal disease higher in 1933 than in 1925 or in 1932; and whether he would now consider the need for legislation to require compulsory notification and segregation of cases of these infectious and disabling diseases on lines similar to those in force under the Infectious Disease (Notification) Extension Act, 1899.—Sir Hilton Young replied : With regard to the first part of the question, the crude death-rate from syphilis per million persons living was the same in 1933 as in 1924, but the standardised rates show a decline. The numbers of new cases attending the treatment centres provided for venereal diseases show an increase over the years mentioned for all forms of venereal disease, but a decline for syphilis. These figures, however, do not necessarily reflect the actual incidence of the disease. With regard to the second part, I see no reason for disagreeing with the Committee of Inquiry of 1923 which came to the conclusion that compulsory measures on the lines suggested were not desirable in the case of these diseases.

Sir A. Wilson : Is the Minister aware that Great Britain is practically the only large country in Europe where the rates have not shown a very substantial decline ?

Sir Francis Fremantle : Does my right hon. friend also realise that Great Britain is the one country where vital statistics are the most real and extensive ?

No further answer was given.

Maternal Mortality, 1934

Mr. George Griffiths asked the Minister of Health the numbers of deaths from and arising out of childbirth for the year ending Dec. 31st, 1934.—Sir Hilton Young replied : Deaths registered in England and Wales in the calendar year 1934 included 2747 classified to pregnancy and childbearing, and 748 not so classified, but returned as associated with those conditions, amounting in all to 3495. The figures are provisional.

Mr. Pike : Is my right hon. friend aware that many of these deaths are due to the fact that there is a considerable lack of maternity services throughout the whole of the industrial areas ?

Sir Hilton Young : No, Sir. The suggestion contained in the question is entirely without justification.

Sir Francis Fremantle : Has my right hon. friend had his attention drawn to the experiment in Rochdale where as a result of intensive propaganda of existing organisations they were able, in the course of three years, to reduce maternal mortality to about one-third of what it was previously ?

Mr. Griffiths : Is it not a fact that there were 51 more deaths than in the previous year and that the percentage is going up ?

Viscountess Astor : Is it not true that people dare not face up to a great many of the causes of maternal mortality, even in the House of Commons, and that until we do face up to some of these causes, such as disease and the lack of birth-control centres, we shall never get down the death-rate ?

Mr. Griffiths : And look after the feeding of the people.

Sir Hilton Young : It has been found to be entirely the case, after investigation, that the causes of maternal mortality are many and varied. It requires most careful investigation into particular cases, and it cannot be ascribed to any single or general cause.

Basement Dwellings in London

Mr. Lyons asked the Minister of Health if any recent investigations had been made into the number and character of basement dwellings in various parts of London; and the conclusions reached or representations made in the matter.—Sir HILTON YOUNG replied: According to returns obtained by the London County Council last year from the Metropolitan Borough Councils there were in London 20,108 underground rooms habitually used for sleeping purposes which were deemed unfit for human habitation within the meaning of Section 18 of the Housing Act, 1925. As regards the latter part of the question, Clause 71 of the Housing Bill now before this House is designed to extend the powers of the local authorities for dealing with basement dwellings.

TUESDAY, MAY 7TH

Temperature in Hot and Deep Mines

Mr. TINKER asked the Secretary for Mines if he was in a position to make a statement in respect of the temperature in hot and deep mines; and if the Hot and Deep Mines Committee or the Safety in Mines Research Board had come to a decision as to what the maximum temperature should be in mines.—Mr. E. BROWN replied: The matter continues to be the subject of general and practical study by a research committee, and of ameliorative action in particular cases. I have not received any recommendation in favour of fixing a maximum limit of temperature.

MEDICAL NEWS

University of Cambridge

On May 4th the following degrees were conferred:—

M.D.—M. H. Salaman and H. E. Nourse.

M. Chir.—F. W. Holdsworth.

M.B., B.Chir.—A. C. E. Cole, G. E. H. Tisdall, A. T. Blair, H. J. V. Morton, Ashton Miller, G. L. Ward, and L. W. B. Dobbin.

M.B.—E. A. M. Halsted (by proxy), W. H. H. Jebb, H. M. Chappel, P. W. Hutton, J. W. Macmillan, T. M. Bell, W. D. Dick, J. W. Maycock, and A. S. Herington.

B.Chir.—R. J. Buxton.

University of London

On May 28th, 30th, and 31st, at 5.30 P.M., at King's College, Strand, W.C., Dr. Daniel de Lange, director of the Hubrecht Laboratory of the Embryological Institute at Utrecht, will lecture on the head problem in chordates. Prof. J. P. Hill, F.R.S., will take the chair at the first lecture.

Royal College of Physicians of London

Licences to practise (in addition to those given in our issue of May 4th) were conferred by the College upon 84 candidates (78 men and 6 women) who have now completed the final examination of the Conjoint Board and have complied with the College by-laws. The following are the names and medical schools of the successful candidates:—

M. P. Adel, St. Bart.'s; J. K. Adranvala, Bombay and Sheff.; D. G. Allen, Camb. and King's Coll.; Minnie Atkin, King's Coll.; E. B. D. Bangay, St. Bart.'s; A. L. W. Bell, Guy's; M. H. Bob, St. George's; H. V. Brown and J. A. G. Carmichael, Guy's; H. B. C. Carter-Locke, St. Thos.; L. J. Clapham, St. Mary's; J. V. Clark, Guy's; P. E. G. Clements, St. Bart.'s; M. Cohen, King's Coll.; S. Cohen, St. Bart.'s; L. Cooperman, Wits'rand and West Lond.; F. F. Croft, St. Bart.'s; A. P. Dale-Bussell, Guy's; M. C. Damkengrit, Camb. and St. Thos.; Debora David, Royal Free; C. E. M. de Gruchy and G. C. Denny, Guy's; E. P. H. Drake, Camb. and St. Bart.'s; F. P. Ellis, Charing Cross; M. A. Falconer, Otago; J. S. Feynman, Middlesex; J. W. Fisher, Westminster; W. P. Fitch, Guy's; R. J. Force-Jones and L. D. B. Frost, St. Bart.'s; R. T. Gabb, Camb. and St. Bart.'s; J. G. Gladston, St. George's; C. J. Gordon, Camb. and St. Bart.'s; G. B. Grayling, St. George's; K. L. Grogono, London; J. A. G. Hair, Univ. Coll.; J. A. J. Hammond, Guy's; W. F. Harvey, Lond.; T. H. Hills, Guy's; E. D. Hoare, Camb. and St. Mary's; J. J. V. Hopkins and H. M. Hugh, St. Bart.'s; Ruth Hull, King's Coll.; R. F. Jarrett, Camb. and St. George's; J. D. Jenkins, Middlesex; D. V. John, Camb. and Univ. Coll.; I. Klinger, King's Coll.; F. H. Lee, Guy's; D. Levine, Cape and St. Bart.'s; I. W. MacKichan, Camb. and Lond.; P. E. C. Manson-Bahr, Camb. and Lond.; J. H. Mayer, Guy's; M. S. M. Mehta, Bombay and Guy's; H. S. Mellows, Camb. and King's Coll.; W. J. Mitchell and J. F. Morris, Guy's; S. J. Navin, St. Mary's; R. J. Niven, St. Thomas's; W. O. G. Paget, St. Bart.'s; J. H. Patterson, Camb. and St. Bart.'s; S. Phillips, King's Coll.; F. O. Potter, Guy's; A. E. K. Price, Middlesex; G. R. Rawlings, Camb. and St. Thos.; W. M. Rich, King's Coll.; J. S. Richardson, Camb. and St. Thos.; W. B. Ridsdel, Camb. and Lond.; E. P. Rigby, St. Bart.'s; Jean Ross, Univ. Coll.; V. Sankarambal, Madras and Royal Free; J. Schorstein, Vienna and Univ. Coll.; D. S. Scott, Camb. and Lond.; M. J. Shah, Bombay and Lond.; F. A. Simmonds, Camb. and St. Thos.; F. R. Smith, Birm.; J. E. Spalding and D. P. Stevenson, Guy's; K. Tatz, Wits'rand and Guy's; F. Taylor, Guy's; W. Warren, Camb. and St. Bart.'s; C. E. Watson, Camb. and St. Thos.; A. B. Wayte, Guy's; Helen E. Wight, Royal Free; and E. D. H. Williams, Guy's.

National Institute of Industrial Psychology

Under the auspices of this institute three lectures on the temperamental factor in industry are to be given at the London School of Hygiene and Tropical Medicine, Keppel-street, W.C., at 5.30 P.M. on Mondays, May 13th, 20th, and 27th. Prof. Major Greenwood, F.R.S., will deliver the first two, and Miss May Smith, D.Sc., the third. Admission is without ticket.

Jubilee Gifts

Mr. Joseph H. Jacobs has given to St. Bartholomew's Hospital the means to install a new 200 kilovolt X ray therapy apparatus in the radiological department.

Indian Research Fund Association

Dr. Wallace Ruddell Aykroyd has been appointed director of nutritional research under this association.

Ministry of Pensions

Lord Dawson, Sir Farquhar Buzzard, and Sir Lisle Webb have been appointed hon. consulting physicians to the Ministry, and Sir Holburt Waring, Lord Moynihan, and Mr. R. C. Elmslie hon. consulting surgeons.

Glasgow University Club

The London branch of this club will hold a dinner at the Trocadero Restaurant, Piccadilly, W., on Friday, May 31st, at 7.15 for 7.30 P.M., when Lord Macmillan, the president, will be in the chair. The honorary secretaries may be addressed at 62, Harley House, London, N.W.1.

Research Fellowships in Tuberculosis

The Dorothy Temple Cross research fellowships in tuberculosis for 1935–36 will shortly be awarded by the Medical Research Council. The object of these fellowships is to give special opportunities for study and research to workers who intend to devote themselves to the advancement by teaching or research of curative or preventive treatment of tuberculosis. Candidates must be British subjects and must possess suitable medical, veterinary, or scientific qualifications; preference will be given to those who wish to make their studies or inquiries outside Great Britain. The value of the fellowships awarded will not be less than £350 per annum, exclusive of allowances, and they will as a rule be tenable for one year. It may also be possible to award a senior fellowship of considerably greater value to a specially well-qualified candidate who wishes to study some particular problem at a chosen centre in another country. Further particulars and forms of application are obtainable from the secretary of the council, 38, Old Queen-street, Westminster, S.W. 1. Application must be made by June 1st.

Welsh National School of Medicine

Mr. Lambert Rogers, F.R.C.S., reader in surgery at the British Postgraduate Medical School, has been appointed director of the surgical unit of the school and professor of surgery in the University of Wales.

Lambert Charles Rogers qualified M.R.C.S. Eng. in 1920 from the Middlesex Hospital, where he held posts as house surgeon and demonstrator in anatomy. He was then appointed resident surgical officer at the Stockport Infirmary and from there he went to the Welsh National School of Medicine as assistant director of the surgical unit. This post he held until his election last year to the readership in surgery at the British Postgraduate Medical School. Mr. Rogers was the Rogers prize essayist of the University of London in 1921, was proxime accessit for the Jacksonian prize of the Royal College of Surgeons of England in 1931, and was elected a Hunterian professor to the College in 1934 (see THE LANCET, 1935, i., 187). He became M.Sc. Wales and F.A.C.S. in 1928, and F.R.A.C.S. in 1931. His chief contributions to medical literature have been on neuro-surgery and the surgery of the thyroid.

Other appointments made were: Dr. Frank Hawking, assistant lecturer in materia medica and pharmacology; Dr. J. M. L. Burtenshaw, assistant lecturer; Dr. R. W. John, demonstrator in pathology and bacteriology; and Mr. Alan Goode, junior assistant in the surgical unit.

Medical Diary

SOCIETIES

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

Tuesday, May 14th.

Therapeutics and Pharmacology. 5 P.M. (House of the Pharmaceutical Society, Bloomsbury-square, W.C.), Annual General Meeting. Demonstrations: J. Plesch: Tonoscillograph. J. Plesch and E. P. Poulton: Apparatus for Increasing Intrapulmonary Pressure in Treatment of Acute Pulmonary Œdema. M. R. Gurd: Reticulocytes in the Blood of the Pigeon. F. Wokes: Estimation of Thyroid. E. Bülbring and J. H. Burn: Vaso-dilator Fibres in the Sympathetic Supply of the Blood Vessels of the Muscles of the Dog. Communications: K. H. Coward: Effect of Cooking on Amount of Vitamin A present in Vegetables. E. Bülbring and J. H. Burn: Estimation of Œstrone in Oily Solution.

Psychiatry. 8.30 P.M. Annual General Meeting. Dr. C. P. Blacker: The Uses and Limitations of Sterilisation in Social Psychiatry.

Thursday.

Dermatology. 5 P.M. (Cases at 4 P.M.) Annual General Meeting. Cases: Dr. Henry MacCormac: 1. Arsenic-resistant Syphilis. Mr. H. Corsi: 2. Case for Diagnosis. ? Lupus Erythematosus. Dr. G. B. Dowling: 3. Sarcoma of the Skin. 4. Morphœa. Other cases will be shown.

Neurology. 7.45 P.M. (National Hospital, Queen-square, W.C.), Annual General Meeting. Cases will be shown.

Friday.

Physical Medicine. 5 P.M. Annual General Meeting.

Radiology. 7 P.M. Annual General Meeting.

Obstetrics and Gynæcology. 8 P.M. Annual General Meeting. Discussion: Diet in Pregnancy. Openers: Dame Louise McIlroy: Diet Requirements in Pregnancy. Dr. G. W. Theobald: The Deficiency Hypothesis of the Toxæmias of Pregnancy. Prof. S. J. Cowell: Calcium Requirement and Calcium Metabolism in Pregnancy.

MEDICAL SOCIETY OF LONDON, 11, Chandos-street, W.

Monday, May 13th.—8 P.M., Annual General Meeting. Sir William Wilcox: Toxic Drugs: Their Use and Misuse. (Annual Oration.)

EUGENICS SOCIETY.

Tuesday, May 14th.—5.15 P.M. (Rooms of the Royal Society, Burlington House, Piccadilly, W.), Prof. R. A. Fisher, F.R.S.: Eugenics, Academic and Practical.

PADDINGTON MEDICAL SOCIETY.

Tuesday, May 14th.—9 P.M. (Great Western Royal Hotel, Paddington, W.), Dr. G. P. Crowden and Dr. P. M. T. Kerridge: The Audiometer and Artificial Aids to Hearing.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE, 26, Portland-place, W.

Thursday, May 16th.—8.15 P.M., Dr. D. H. K. Lee: The Human Organism and Hot Environments.

BRITISH INSTITUTE OF RADIOLOGY, 32, Welbeck-street, W.

Thursday, May 16th.—8 P.M., Mr. G. Shearer: The X Ray Microscope. (Presidential Address.)

Medical Section.

Friday, May 17th.—11 A.M., Visit to the X Ray Department of the Middlesex Hospital. 5 P.M., Case Demonstration and Discussion.

ROYAL MEDICO-PSYCHOLOGICAL ASSOCIATION.

Thursday, May 16th.—2.30 P.M. (11, Chandos-street, W.), Dr. A. A. W. Petrie: Mental Health Services.

TUBERCULOSIS ASSOCIATION.

Friday, May 17th.—5.15 P.M. (2
Dr. H. P. Nelson and Dr. Pete
Paralysis of the Diaphragm.
Kerley and Dr. J. V. Sparks:
and the Interpretation of Radiographs.

ROYAL MICROSCOPICAL SOCIETY.

Wednesday, May 15th.—5 P.M. (B.M.A. House, Tavistock-square, W.C.), Mr. R. S. Clay and Mr. T. H. Court: The Early Achromatic Objective. Dr. G. M. Findlay: Variation in Viruses.

SOCIETY OF CHEMICAL INDUSTRY.

Monday, May 13th.

London Section.—8 P.M. (Chemical Society's Rooms, Burlington House, W.), Prof. F. L. Pyman, F.R.S.: Some Lines of Research in Chemotherapy.

LONDON JEWISH HOSPITAL MEDICAL SOCIETY.

Sunday, May 12th.—8.30 P.M. (44, Lancaster-gate, W.), Prof. C. Seligman: Some Aspects of Race Psychology. (Annual Oration.)

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF PHYSICIANS OF LONDON, Pall Mall East, S.W.

Tuesday, May 14th, and Thursday.—5 P.M., Sir Edmund Spriggs: A Clinical Study of Headaches. (Croonian Lectures.)

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

Monday, May 13th, to Saturday, May 18th.—Brompton Hospital, S.W. All-day course in thoracic surgery.—Maudsley Hospital, Denmark-hill, S.E. Afternoon course in psychological medicine.—St. John's Hospital, Leicester-square, W.C. Afternoon course in dermatology. (Open to all.)—Courses arranged by the Fellowship are open only to members and associates.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C.

Thursday, May 16th.—2 P.M., Mr. James Crooks: Infection of the Ear and Sinuses. 3 P.M., Dr. W. W. Payne: Carbohydrate Metabolism.

Out-patient clinics daily at 10 A.M. and ward visits (except on Wednesday) at 2 P.M.

WEST LONDON HOSPITAL POST-GRADUATE COLLEGE, Hammersmith, W.

Monday, May 13th.—10 A.M., Medical and Surgical Wards, Genito-urinary Operations, Skin Clinic. 2 P.M., Gynæcological and Surgical Wards, Eye and Gynæcological Clinics.

Tuesday.—10 A.M., Medical Wards. 11 A.M., Surgical Wards. 2 P.M., Nose, Throat, and Ear Clinic.

Wednesday.—10 A.M., Medical Wards, Children's Wards and Clinic. 2 P.M., Gynæcological Operations and Eye Clinic.

Thursday.—10 A.M., Neurological and Gynæcological Clinics. 12 noon, Fracture Demonstration. 2 P.M., Genito-urinary and Eye Clinics. 3.45 P.M., Venereal Diseases Clinic.

Friday.—10 A.M., Skin Clinic. Noon, Lecture on Treatment. 2 P.M., Throat, Nose, and Ear Clinic.

Saturday.—10 A.M., Medical Wards, Children's and Surgical Clinics.

Operations, Medical and Surgical Clinics daily at 2 P.M.

LONDON SCHOOL OF DERMATOLOGY, 49, Leicester-square, W.C.

Monday, May 13th.—5 P.M., Dr. R. T. Brain: Rodent Ulcer.

Tuesday.—5 P.M., Dr. H. MacCormac: Treatment of Syphilis.

Wednesday.—5 P.M., Dr. I. Muende: Pathological Demonstration.

Friday.—5 P.M., Dr. W. Griffith: Bullous Eruptions.

CENTRAL LONDON THROAT, NOSE, AND EAR HOSPITAL, Gray's Inn-road, W.C.

Monday, May 13th, to Saturday, May 18th.—Intensive Clinical Course.

ST. MARY'S HOSPITAL, W.

Thursday, May 16th.—5 P.M. (Institute of Pathology and Research), Dr. Igor N. Asheshow: Bacteriophage.

INSTITUTE OF MEDICAL PSYCHOLOGY, Malet-place, W.C.

Wednesday, May 15th.—3 P.M., Dr. H. Crichton-Miller: Anxiety. 4.30 P.M., Dr. Cedric Shaw: Hyperthyroidism.

NATIONAL INSTITUTE OF INDUSTRIAL PSYCHOLOGY.

Monday, May 13th.—5.30 P.M. (at the London School of Hygiene and Tropical Medicine, Keppel-street, W.C.), Prof. M. Greenwood, F.R.S.: The Modern Importance of the Temperamental Factor and its Ancient History. (Course of three lectures on the Temperamental Factor in Industry.)

UNIVERSITY OF BIRMINGHAM.

Tuesday, May 14th.—3.30 P.M. (General Hospital), Dr. E. W. Assinder: V.D. Cases of Interest.

(Anatomy Theatre, The Univer-
Dr. Howard Collier: Industrial

Friday.—3.30 P.M. (Children's Hospital), Dr. W. Carey Smallwood: Diagnosis and Treatment of Chronic Bronchitis and Bronchiectasis in Infancy and Childhood.

UNIVERSITY OF LONDON.

Monday, May 13th.—5 P.M. (University College), Dr. D. H. K. Lee: Physiological Effects of Tropical Climate. (First of four lectures.)

UNIVERSITY OF DURHAM COLLEGE OF MEDICINE.

Sunday, May 12th.—10.30 A.M. (Newcastle General Hospital), Mr. J. Collingwood Stewart: Abdominal Distension and its Significance.

ROYAL INFIRMARY, Manchester.

Tuesday, May 14th.—4.15 P.M., Dr. William Brockbank: Lung Cancer.

Friday.—4.15 P.M., Mr. J. P. Buckley: Demonstration of Surgical Cases.

GLASGOW POST-GRADUATE MEDICAL ASSOCIATION.

Wednesday, May 15th.—4.15 P.M. (Victoria Infirmary), Dr. W. Herbert Brown: Skin Cases.

ROYAL INFIRMARY, Dundee.

Thursday, May 16th.—3.15 P.M., Cinematograph film: The Science and Art of Obstetrics.

Appointments

Ellis, G. R., M.B. Camb., M.R.C.P. Lond., has been appointed Hon. Assistant Physician to the General Hospital, Birkenhead.

Gray, W. A., M.B. Edin., F.R.C.S. Eng., Ophthalmic Surgeon to the Corporation of Barking.

Kelynack, A. V., M.B. Lond., reappointed Senior Resident Medical Officer to the Royal Free Hospital.

Masterson, T. L., M.D. St. And., F.R.C.S. Edin., Resident Surgical Officer to the Huddersfield Royal Infirmary.

McFarland, B. L., M.D., M.Ch. (Orth.) Liverp., Hon. Orthopædic Surgeon to the Royal Southern Hospital, Liverpool.

Richmond, Arthur, M.B. Victoria, D.P.H., Medical Officer of Health to the Berkshire County Council.

SACHS, LEONARD, M.D. Bern., L.M.S.S.A. Lond., Resident Medical Officer to the Royal Bath Hospital, Harrogate.

City of London Hospital for Diseases of the Heart and Lungs.—The following appointments are announced:—
HUDSON, E. H., M.B. Camb., M.R.C.P. Lond., Out-patient Physician;
WOOD, F. G., M.B., D.M.R.E., Radiologist;
RUSBY, N. L., B.M. Oxon., M.R.C.P., Registrar; and
GRANT, C. A., M.R.C.S. Eng., D.M.R.E., Assistant Radiologist.

Royal Borough of Kensington.—The following appointments are announced:
HUNTER, J. W., M.D. Edin., D.P.H., Deputy Medical Officer of Health and Tuberculosis Officer.
BUCK, Helen, M.B. Lond., D.C.O.G., Maternity and Child Welfare Medical Officer.
DAVIS, H. M., M.B. Liverp., D.P.H., Maternity and Child Welfare Medical Officer.

Certifying Surgeons under the Factory and Workshop Acts: Dr. W. M. MARTIN (Peebles, Peebleshire); Dr. A. H. DRIVER (Leominster, Herefordshire); and Dr. A. MENZIES (Youlgreave, Derbyshire).

Vacancies

For further information refer to the advertisement columns

[illegible]—Ophthalmic Surgeon.
[illegible] I.O. At rate of £150.
[illegible] *ry.*—Cas. O. £250.
[illegible] it and Cas. O. £150.
[illegible] ond H.S. At rate of
[illegible] H.P. At rate of £150.
[illegible] *Hospital.*—Two Asst. Res. M.O.'s. Each at rate of £150.
Birmingham, Canwell Hall Babies' Hospital.—Res. M.O. At rate of £250.
Birmingham City Maternity and Child Welfare Dept.—Temporary M.O.'s. Each £10 per week.
Bolingbroke Hospital, Wandsworth Common, S.W.—H.S. At rate of £120. Also Hon. Phys. for Dis. of Children.
Bolton Royal Infirmary.—Two H.S.'s. Each £125.
Bradford, Royal Ear and Eye Hospital.—H.S. £160.
Brighton, Royal Sussex County Hospital.—Second Hon. Radiologist.
Burton-on-Trent General Infirmary.—Cas. O. and H.P. £150.
Cambridge, Physiology School.—George Henry Lewes Studentship. £250.
Cancer Hospital, Fulham-road, S.W.—Asst. Radium Officer. £350.
Cardiff, King Edward VII Welsh National Memorial Assn.—Asst. Tub. Physician. £500.
Cardiff, Welsh National School of Medicine.—Part-time Demonstrator. £50. Also Jun. Asst. in Medical Unit. £250.
Central London, Throat, Nose, and Ear Hospital, Gray's Inn-road, W.C.—Third Res. H.S. At rate of £75.
Chester Royal Infirmary.—H.S. £150.

Coventry, Gulson-road Municipal Hospital.—Second Asst. Res. M.O. £250.
Coventry and Warwickshire Hospital.—H.S. for Aural and Ophth. Depts. At rate of £125.
Derbyshire Royal Infirmary.—Ophth. H.S. and Anæsthetist. £150.
Ealing Borough.—Asst. M.O. £450.
Evelina Hospital for Sick Children, Southwark, S.E.—H.S. At rate of £120.
Fulham Hospital, St. Dunstan's-road, W.—Asst. M.O. £350.
Greenwich, Dreadnought Hospital.—Asst. Radiologist. 50 gns.
Grimsby Corpora[illegible] I.O. £350.
Halifax General [illegible] O. £250.
Hastings, Royal [illegible] -Hon. Phys.
Herefordshire General Hospital.—H.S. and Cas. O. At rate of £100.
Hospital for Consumption and Diseases of the Chest, Brompton, S.W.—Asst. for Dept. of Pathology. £350.
Hospital for Sick Children, Great Ormond-street, W.C.—H.P. and H.S. Each at rate of £100.
Hull Royal Infirmary.—Cas. O. At rate of £150.
Huntingdon Administrative County.—Asst. County M.O. and Asst. School M.O. £50 a month.
Indian Medical Service.—Commissions.
Iraq Governme[illegible] ach £100–£120 per mensem.
King George [illegible] Surg. O. and Res. Asst. Surg. O. [illegible] ectively. Also Two H.P.'s and Three H.S.'s. Each at rate of £100.
King's College Hospital, S.E.—Registrar to Ear, Nose, and Throat Dept.
Lincoln County Hospital.—Jun. H.S. At rate of £150.
Liverpool, Cleaver Sanatorium for Children, Heswale.—Res. Asst. M.O. £300.
[illegible] *Forest, Frodsham.*—Second Asst.
[illegible] *ol, South Norwood, S.E.*—Part-
[illegible] to Gyn. and Obstet. Dept.
[illegible]—Second H.S. At rate of £150.
[illegible] *almic and Aural Hospital.*—H.S. [illegible] Dept. At rate of £200.
Manchester, Ancoats Hospital.—Cas. O. At rate of £250. Med. Reg. £50. Also H.S. At rate of £100.
Manchester, Monsall Hospital for Infectious Diseases.—Asst. M.O. £350.
Manchester, Park [illegible] Surg. O. £500.
Manchester Royal [illegible]). in Radiological Dept. £350. [illegible] £35.
Manchester, Victor [illegible] . Royce Research Fellowship. £500.
Manchester and Salford Hospital for Skin Diseases, Quay-street.—Two Asst. M.O.'s. Each £100. Also H.S. At rate of £100.
Miller General Hospital, Greenwich-road, S.E.—Out-patient Officer and Two Cas. O.'s. Each at rate of £150. Also H.P. and H.S. Each at rate of £100.
National Hospital for Diseases of the Nervous System, Queen-square, W.C.—Registrar. £200.
Newcastle-upon-Tyne Eye Hospital.—Jun. Res. H.S. £150.
Northampton County Mental Hospital, Berrywood.—Jun. Asst. M.O. £350.
Oswestry, Robert Jones and Agnes Hunt Orthopædic Hospital.—H.S. At rate of £200.
Oxford, Wingfield-Morris Orthopædic Hospital.—H.S. £100.
Plymouth, Prince of Wales's Hospital, Devonport.—H.P. and Cas. O. At rate of £100. Also Res. Surg. and H.S. At rate of £200 and £120 respectively.
Preston, Sharoe Green Hospital.—Sen. Asst. Res. M.O. At rate of £150.
Queen Charlotte's Maternity Hospital, Marylebone-road, N.W.—Asst. Res. M.O. At rate of £80.
Radium Institute, Riding House-street, W.—H.S. At rate of £150.
Reading, Royal Berkshire Hospital.—Cas. O. and H.S. Each £125.
Royal College of Surgeons of England.—Two Examiners in Dental Surgery. Also Court Examiners.
Royal Free Hospital, Gray's Inn-road, W.C.—First Asst. in Children's Dept. At rate of £115.
Royal Northern Hospital, Holloway, N.—Res. M.O. £370. Also H.S. and H.P. Each at rate of £70.
Royal Waterloo Hospital for Children and Women, Waterloo-road, S.E.—Cas. O. £200. Also H.S. At rate of £100.
St. George-in-the-East Hospital, Raine-street, E.—Asst. M.O. £250.
St. Giles' Hospital, Brunswick-square, S.E.—Clin. Asst. At rate of £150.
St. Helens County Borough.—Deputy M.O.H. £700.
St. James' Hospital, Ouseley-road, S.W.—Asst. M.O. £250.
St. Luke's Hospital, Sydney-street, S.W.—Asst. M.O. £350.
Sheffield Royal Infirmary.—H.P. At rate of £80. Also Clin. Asst. £300.
Southampton, Royal South Hants and Southampton Hospital.—Cas. O., Res. Anæsthetist, and H.S. Also H.S. Each at rate of £150.
Southend-on-Sea General Hospital.—Med. Reg. £300. Surg. Reg. £250. Also Cas. O. At rate of £100.
[illegible] sst. M.O. £600.
[illegible] . and Jun. H.S.'s. £200.
Stoke-on-Trent, Longton Hospital.—H.S. £160.
Sunderland Royal Infirmary.—H.P. and H.S. Each £120.
Talgarth, Breconshire, Mid-Wales Counties Mental Hospital.—Asst. M.O. £350.
Taunton and Somerset Hospital.—H.S. At rate of £100.
Truro, Royal Cornwall Infirmary.—H.S. £170.
University College Hospital Dental School, University-street, W.C. Demonstrator in Mechanical Dept. £200.
Wembley Urban District Council.—Part-time Clinic M.O. £1 11*s.* 6*d.* per session.
West End Hospital for Nervous Diseases, Regent's Park.—Hon. Anæsthetist.
West Bromwich and District General Hospital.—H.P. At rate of £200.
Wolverhampton, Royal Hospital.—H.S. At rate of £100.
Wolverhampton and Midland Counties Eye Infirmary.—H.S. £150.
Woolwich and District War Memorial Hospital, Shooters Hill, S.E. H.P. and H.S. Each at rate of £100.
York City.—Sen. Asst. School M.O. Also Asst. School M.O. Each £500. Also Temp. Asst, M.O. £500, and Temp. Res. M.O. £250.

The Chief Inspector of Factories announces a vacant appointment for a Certifying Factory Surgeon at Llanberis, Caernarvonshire.

Births, Marriages, and Deaths

BIRTHS

ATKINS.—On April 29th, at Devonshire-place, W., the wife of Hedley Atkins, F.R.C.S. Eng., of a son.

HODGKINSON.—On May 5th, at Lymington, Hants, the wife of H. Ll. Hodgkinson, M.R.C.S. Eng., of a son.

MARRIAGES.

BERRY—INGRAM.—On May 4th, at the Parish Church, Wimbledon, Sir James Berry, F.R.C.S. Eng., of Wendover, to Mabel Marian, daughter of the late T. Lewis Ingram and Mrs. Ingram, of The Priory, Wimbledon Common.

TWEED—HOGGE.—On May 2nd, at St. Matthew's, Ealing, W., James G. Tweed, M.B. Belf., to Betty Josephine Hogge.

DEATHS

BROOKS.—On April 28th, Francis Augustus Brooks, M.D. Brux., M.R.C.S. Eng., of Lonsdale-road, W., in his 73rd year.

FFENNELL.—On May 3rd, at Walton, Clevedon, Edward Barrington Ffennell, M.D. Dub., aged 72 years.

STAMFORD.—On May 4th, suddenly, at Loughborough, Robert Basil Stamford, F.R.C.S. Edin.

WALKER.—On April 30th, Horace Walker, M.R.C.S. Eng., late of Hammersmith.

WHARRY.—On April 27th, at Whitstone Head, Holsworthy, N. Devon, Robert Wharry, M.D. Aberd., in his 82nd year.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

NOTES, COMMENTS, AND ABSTRACTS

GUY'S HOSPITAL: PROFITABLE ENTERPRISE

AMONG the statements of account which have recently been presented to the governors of Guy's Hospital on the working of the year 1934, one deals with the cost of feeding the nursing, administrative, and domestic staff of the hospital. It is stated that though the food provided is generous and of good quality, containing a substantial allowance of meat, fish, butter, and plenty of eggs, vegetables, and other foodstuffs, yet the cost to the hospital of feeding its nursing and other staff works out at only 6*s*. 6*d*. a week per head. It is clear that, even when the reduction in price of food bought in large quantities is taken into consideration, good and sufficient food cannot be provided at such a low cost without very wise buying and expert handling of materials. Another statement shows that the whole cost of housing the nurses, including repairs and maintenance of the nurses' homes, insurance and rates on them, wages of maids, renewals of furniture, bedding, hardware and crockery, cleaning materials, staff uniforms, and laundry, works out at a fraction less than 10*s*. a week per head. At this hospital, at any rate, the emoluments of the probationers and nurses amount to less than the rate of £50 a year at which they are assessed in the Federated Superannuation Scheme for Nurses and Hospital Officers.

A statement is also made on the year's working of Guy's Hospital shop. This was started a few years ago in a kind of large kiosk in the hospital grounds for the benefit of patients and nurses, and is now quite a flourishing little business, making a profit for the hospital funds. The shop sells all manner of goods likely to be needed by patients, who send their orders from the wards by their visiting relations, or by voluntary helpers who take trays of things like sweets and tobacco, and lists of other items stocked by the shop, round the wards from time to time. The stock includes biscuits, cakes, and light foodstuffs, including ice-cream, all kinds of haberdashery, and articles of clothing such as night-wear, bed-jackets, or such garments as patients brought into the hospital unprepared, or staying longer than they had anticipated, might need. The account for the year 1934 shows that the shop, after paying all expenses—salaries, repairs, electricity, gas and water, cleaning, rent, and rates—made a profit on trading of 19·5 per cent., which represents £462 19*s*. 1*d*. in cash.

Another profit-making section of the hospital is its paying patients' ward, a pioneer institution of its kind, having been first started over 30 years ago. From a financial point of view the ward is run as a separate unit, and when all expenses, including rent, rates, and taxes, and proportion of administration, have been deducted from income, the profit for the year 1934 is shown as over £3000.

Still another successful enterprise of Guy's is its electricity generating station, which supplies all current required for the manifold demands of this great hospital at a cost which works out at approximately 0·7*d*. a unit.

THE LEVEL OF AMPUTATION

WE have already summarised some of Prof. René Leriche's invective against rapid amputations slavishly reproducing those of the operative surgery class (Jan. 5th, p. 38). In the same paper he pointed out that amputation in the presence of local circulatory failure has problems of its own, and unless there is moist gangrene and spreading septic infection it rarely need be looked on as an emergency operation. There is time, he said, to consider in detail the indications for amputation at a particular level; and sometimes it is profitable to try to increase the efficiency of the circulation and thus the chances of successful healing at a lower level.

Writing on the same subject last year, R. W. McNealy and Philip F. Shapiro (Surg., Gyn., and Obst., 1934, lix., 650) suggested that safety is too often sought by amputating above the knee, wh a careful investigation would have saved the patie from a needlessly mutilating operation. In at lea one class of case—commencing gangrene of the to in thrombo-angiitis obliterans—this consideration of great importance, for the patients are often you and active. The other two main causes of loc vascular failure are arterio-sclerosis and diabete and here, of course, general principles of saving li may come before attempts to save six inches more of a limb which the patient is never likely put to much use. The type of gangrene in diabet which is infective in origin is, however, to be disti guished from that due to early arterio-sclerosis, sin it does not necessarily require more than a limite amputation.

McNealy and Shapiro gave a detailed account the tests they use in deciding on the level of amput tion. The decision most often lies between amput tion of a toe, amputation through the leg 6–9 inch below the knee-joint (which is the best level) or 4–6 inches (which gives a good enough stump), amputation through the thigh. They dismiss amp tations between these levels as not being very usef *in fitting the artificial limb. A good idea of circulato* efficiency can usually, they find, be gained from t history and clinical tests. Amputation below t knee, for example, is likely to be feasible if pulsati is palpable in the popliteal artery, and if the temper ture and colour tests are good as far down as t ankle. The colour test is especially important; t limb is raised and the level of the anæmia note as also the level of the rubor appearing when t limb is dropped. Two special methods have al proved helpful. An oscillometer is used to deci the level of pulsatile *collateral* supply, as distin from palpable pulsation in the large vessels; an histamine solution (1 : 1000) is injected intr cutaneously because it will produce definite sk changes only in an adequately vascularised zone These changes are a cyanotic flush, a hyperæmi flare, and finally a weal.

A HANDY EPIDIASCOPE.—The cost of an epidia scope, in many cases the main objection to its instal lation, has been further reduced by Messrs. Newto and Co., of Wigmore-street, London. The "Wigmore" Epidiascope, a satisfactory instrument for class-room purposes, can be obtained for about £16. Its projectio distance may be as great as 14 feet, and a picture a large as 7 feet in diameter can be produced. This wil no doubt be a valuable addition to the epidiascope of British manufacture now available at a reasonabl price.

HUTCHINSON'S TECHNICAL AND SCIENTIFIC ENCY CLOPÆDIA, in three volumes of which the first i before us, has been planned to supply the studen and the teacher with a description of processes tha will enable them to understand how science is applie in industry. The work covers a very wide fie and the articles which vary from a line or two four or five pages, are from the pens of acknowledg experts. The book is edited by Mr. C. F. Twene already well known in the production of simil compilations, and Mr. I. P. Shirshov, A.M.I.E. to whom readers who desire a reference to addition sources of information will be grateful for the bibli graphy promised them at the end of the complete encyclopædia. Medicine is only dealt with inc dentally, the article on bacteria, for instance, bein concerned with industrial processes rather tha disease, but there are short but useful paragraph under such headings as Adrenalin, Antiseptics Carotene, Cod-liver Oil, and so forth, and we lear that Annatto is used chiefly for colouring chees and butter—although it is now illegal in milk. This volume of the Encyclopædia contains 672 pages and costs 28*s*.

ADDRESSES AND ORIGINAL ARTICLES

VISION
) ITS DISTURBANCES IN RELATION TO CEREBRAL LESIONS *

WILFRED HARRIS, M.D. Camb., F.R.C.P. Lond.
LTING PHYSICIAN TO ST. MARY'S HOSPITAL, AND SENIOR PHYSICIAN TO THE HOSPITAL FOR NERVOUS DISEASES, MAIDA VALE

(WITH ILLUSTRATIONS ON PLATE)

SUAL organs in animals have been developed ding to their needs, and vary in complexity from hes of pigmented epithelium, as in the median of amphioxus, perhaps the lowest of the verte-s, to the highly developed paired eyes of the efish and squids amongst the mollusca. These r require keen vision, as they rapidly change colour reflexly according to the colour of the bottom as they swim along, and also for the uit of their prey.

the lowest class of fishes, the cyclostomata, the rey, and hag fish, the optic nerves are budded from the sides of the mesencephalon, and do decussate, but in the elasmobranchs (sharks, &c.) and all the bony fishes, birds, and mammals, optic nerves decussate in the chiasma. In some ivorous fishes, such as the porbeagle and fox ks, and in most carnivorous birds, such as hawks, , and vultures, and in many gulls, such as the et, the eyes are set forward on the face at such ngle that a considerable degree of binocular n is possible, and it is obvious that this arrange- must be of considerable assistance to these , who have to hunt for and catch their rapidly ing prey; particularly is this so in many owls, cially the common barn owl. These birds, being urnal, require a more accurate vision than ks, who work by day. The wonderful keenness ight of vultures is well known, how quickly they ear out of the blue empyrean when an animal dying; but accuracy of striking is less necessary heir case than in owls, and their eyes are not ed as far forward as in the latter.

et in all fishes and birds, whether vegetable ers or carnivorous, whether their eyes are set rally with panoramic vision or forwards on the with binocular vision, the optic nerves decussate pletely, every fibre crossing to the opposite lobe. It is not until we reach the mammals that s of semi-decussation of the optic nerves is . In animals with completely laterally set eyes, as the hare and rabbit, whose food does not way from them and whose panoramic vision ful to them in seeing their food or an enemy her side at a distance, the optic nerves decussate ically completely; yet it is possible to demon- microscopically that a few fibres do pass d from the optic nerve into the optic tract e same side. These animals have no binocular n, and it is well known that a hare may run ght forwards towards the gun, as it cannot see ght in front.

e object of binocular vision is well seen by a of the chameleon.[1] This little animal has us eyes ensheathed in horny epidermis, and the eyes work quite independently of each other, moving about in a jerky fashion, almost like searchlights. One may be pointing backwards and the other forwards, but if the animal catches sight of a juicy morsel, such as a mealworm held up a few inches in front of him, presently one eye will catch sight of it and then the other eye is swept round, both eyes being focused accurately upon the worm, the mouth then slowly opening and the tongue suddenly shot out, like a boomerang, to catch its prey and sweep it into its mouth.

In carnivorous animals binocular vision becomes well marked, especially so in the felidæ, cats, lions, and tigers, whose eyes are set practically as far forward as in the primates. These animals hunt particularly by night, and having to catch living prey consequently require keen vision, the eyes therefore being set far forward in the head, and section of the chiasma shows that a very considerable bundle of the nerve-fibres does not decussate, passing round into the optic tract on the same side. These animals, therefore, have developed stereoscopic in addition to binocular vision, the two images from the two eyes being overlaid on the same area of visual cortex on each side. When we examine the primates, monkeys, anthropoids, and man, binocular vision is even more fully developed, and though all monkeys and the anthropoid apes are vegetable feeders and do not have to catch living prey, yet now the value of binocular stereoscopic vision is associated with the development of the hand as a prehensile organ, objects seized being subject to careful inspection by vision. Section of the chiasma shows an even larger non-decussating bundle, though even in man the decussating bundle is much the larger of the two.

Optic Chiasma

Owing to the semi-decussation of the optic nerves at the chiasma and the relationships of these fibres to the sphenoid bone underneath, the pituitary fossa below and behind, and the third ventricle above, localised damage of these fibres can be produced in various ways. A fracture of the base may pass through the middle line of the sphenoid, damaging the central fibres of the optic chiasma, causing a typical bitemporal hemianopia. There was a case of this recently in St. Mary's Hospital, and I have seen at least two other examples. From above, pressure on the dorsum of the chiasma may be produced through distension of the third ventricle in hydrocephalus resulting from meningitis, or in cerebellar tumours. (Fig. II. on Plate.) This may cause bitemporal hemianopia followed by complete blindness and optic atrophy. Septic infection of the sphenoidal sinus may affect the optic nerve between the chiasma and the optic foramen, causing local damage of the optic nerve, with varying effects upon vision. The optic nerve itself at the optic foramen may be damaged by fracture, or by tumour of the sphenoid compressing the nerve, causing ultimate blindness.

Some of the most important defects in the visual fields are produced by diseases affecting the pituitary gland. This gland, lying in the sella turcica, is formed developmentally by an upgrowth in the median line of the nasopharynx, called Rathke's pouch, which meets a down-growth from the tuber cinereum in the floor of the third ventricle, called the infundibulum. This infundibulum, which becomes the posterior lobe of the pituitary gland, is enclosed within Rathke's pouch, which forms the anterior

---

clinical lecture delivered at St. Mary's Hospital on ith, 1935.
9

lobe and the pars intermedia, the infundibular stalk passing through a diaphragm in the dura mater to reach the floor of the third ventricle. Though the anterior lobe is developed in a somewhat similar fashion to the thyroid gland, yet its endocrine function is very different, largely governing growth and the generative functions, while the posterior lobe secretes a pressor substance, which has a profound effect on raising blood pressure, an intestinal and uterine stimulant, and a galactagogue. It also stimulates carbohydrate metabolism, and its absence leads to excessive deposition of fat.

Giantism

Overgrowth of the anterior lobe, with increased secretion, in young people produces giantism, so long as the epiphyseal junctions of the bones are not ossified.

We need not perhaps accept at their face value the traditional height of Gog and Magog, whose 14 ft. effigies stand in the Guildhall, or the Biblical heroes, Goliath of 11 ft. 9 in., or Og, the king of Bashan, whose bedstead measured 16½ ft. in length. Extraordinary growth has been recorded in certain instances, the recorded limit of height for an English giant, John Middleton, born in 1578, being 9 ft. 3 in., and a Russian, Machnow, with a height of about 9 ft. 5 in. was shown at the Hippodrome in 1905. The skeleton of the Irish giant Patrick Cotter, is still to be seen in Trinity College, Dublin, 8 ft. 7 in. in height, and the well-known skeleton of O'Byrne in the museum of the Royal College of Surgeons, 8 ft. 4 in., which John Hunter procured in a very romantic way.

Giants have been divided into two groups, normal and pathological, but it is highly probable that excessive anterior lobe pituitary activity in the form of a chromophile adenoma is the cause of excessive growth above 6 ft. 9 in., and such giants usually are physically weak or lose their strength comparatively early and die young, while a much enlarged sella turcica has been repeatedly demonstrated e.g., Cushing's[3] case of 8 ft. 4 in. Acromegalic features, such as abnormally long arms and legs, and hands and feet large out of proportion are also usually present. In addition to these great heights, the extremities in some of these individuals were more than correspondingly large, John Middleton's hand measuring 17 in., and the foot of the Russian Machnow, 24 in.

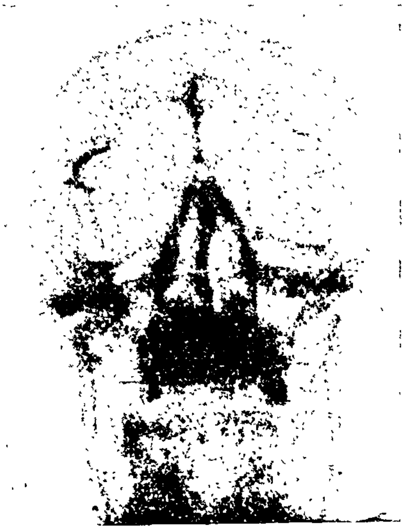

FIG. III.—*Acromegalic skull. Anterior view* (× ⅙).

Acromegaly

When the hyperactivity of the anterior lobe of the pituitary begins to take effect later in life, after the bony epiphyses have become set, then excessive height is no longer possible, but the skeleton and body take on the curious features known as acromegaly. The disease was first described and named by Pierre Marie in 1886, though the characteristic appearance must have been not unfamiliar through the ages, for a thirteenth century stone statue of a woman, an obvious sufferer from the disease, is, or was, to be seen on Reims cathedral.[3] The word means enlargement of the extremities, and the hands and feet take on a curious overgrowth, the hands becoming spade-like; the skull increases in size so that larger and larger sizes in hats become necessary, the lower jaw much enlarged and protruded, with the lower teeth perhaps ¾ in. in front of the upper, the teeth being spaced, and the tongue and lower lip, and the nose and ears enlarged and often somewhat cyanosed. Often the arms are abnormally long, and there is kyphosis of the spine. Sometimes for years there is excessive muscular strength and sexual power associated with slight giantism and acromegaly, but ultimately, in later middle life, muscular weakness and impotence supervene as the gland begins to lose its function.

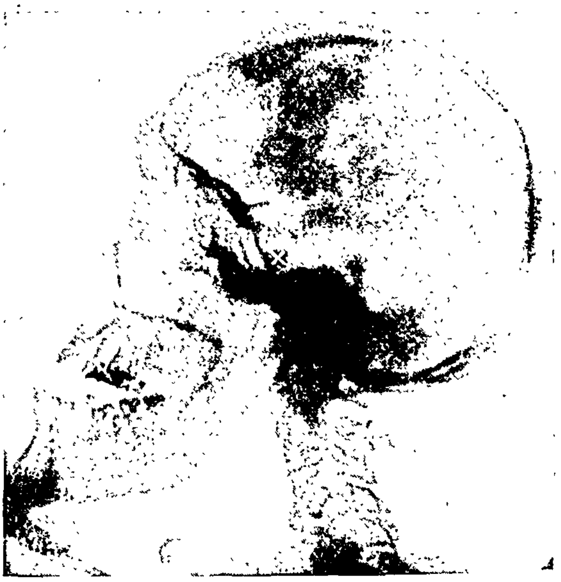

FIG. IV.—Lateral view of skull shown in Fig. III. The sella is much enlarged and the mandible hypertrophied and underhung. No affection of vision.

The general appearance in a well-marked case of the disease has suggested a reversion to anthropoid characteristics, and a radiogram (Fig. III.) of an anterior view of the skull of a patient shows the massive, almost gorilla-like, appearance of the facial bones. A lateral view of the skull (Fig. IV.) shows a much enlarged sella turcica due no doubt to the presence of a chromophile adenoma of the pituitary; yet the patient's vision has not suffered from any signs of pressure upwards on the optic chiasma. Drowsiness has been a feature in this case, due probably to interference by pressure with the function of the tuber cinerum above, and this patient has often missed his station by sleeping in the train, and even has fallen asleep playing cards. This symptom has improved under treatment with thyroid extract, and his neck has also become smaller; he formerly required a 19½ in. collar, and he takes size 8 in hats.

Pituitary Infantilism

Pituitary infantilism, due to arrest or nondevelopment of function of the anterior lobe, is one of the varieties of dwarfs, who are often perfectly formed, and they are not infrequently seen in circus side-shows, or on a music hall stage dressed in female garments and trained for singing and dancing.

Infantile characters persist in the treble voice, the absence of hairy development, and immature generative organs. Mentally also they are somewhat immature.

Very tiny people are sometimes met with, one of the smallest on record being Jeffery Hudson, only 18 in. high, in the service of the first Duke of Buckingham, who had him served up in a cold pie at a dinner given to Charles the First, and his Queen. Jeffery Hudson is recorded to have fought two duels, one with a turkey cock and another with a Mr. Crofts, whom he shot dead from horseback.

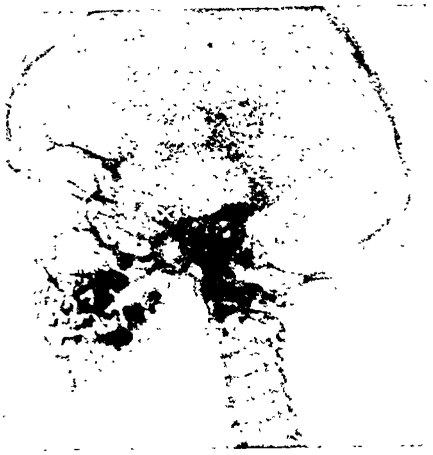

FIG. V.—Lorain infantilism due to cystic adamantinoma. Note "hammered metal" appearance of skull. Enlarged sella with calcareous deposits in tumour. Bitemporal hemianopia. This radiogram has been reduced to about a quarter of its width, but the sella is shown (natural size) in Fig. V.A on the Plate.

In another type of tumour of the anterior portion of the gland in infancy, known as adamantinoma, which grows from Rathke's pouch, the gland is degenerated from the first, and may become cystic as well as tumefied. In these cases the normal growth is inhibited, and the patient shows the well-known signs of infantilism, as described by Lorain, and by Fröhlich, obesity in the latter form being superadded to infantilism when the posterior lobe of the gland is also destroyed.

A typical case is a boy of 13, in whom, at operation, a large cystic adamantinoma of the pituitary was found enclosing a greenish fluid full of cholesterin. He stopped growing and began to put on fat two years ago, and lately at school, owing to complaints of his sight, his eyes were examined and papillœdema was found, for which reason he was sent to St. Mary's Hospital. Here we found typical bitemporal hemianopia, or blinker fields, and X ray (Fig. V.) (and V.A on Plate) of the skull showed an enlarged sella and evidence of a sellar tumour spreading upward, with calcareous deposits.

In this and other tumours of the anterior lobe of the pituitary there is a likelihood of pressure upwards and forwards against the optic chiasma, the lower decussating fibres therefore suffering first, with corresponding defects in vision, affecting primarily the upper quadrants. Scotomata will be bitemporal, though usually much more marked in one eye than the other, the initial visual defect being usually a peripheral scotoma in the upper temporal field of one eye only. As the disease advances and the pressure becomes greater on the optic fibres, the temporal scotoma increases, becoming quadrantic, and later involving the whole half field, while the temporal field in the opposite eye begins also to show defects, till at last complete bitemporal hemianopia, or blinker fields, becomes established. The hemianopic pupil, Wernicke's sign, has been described as present in such cases by several writers, but I was unable to demonstrate it in the boy described above, although his temporal fields were completely blind even to a brilliant light up to the midline and fixation point; his pupil reacted equally smartly from either direction. It is a very difficult sign to test for, as it is necessary to use a fine pencil of parallel rays of light so as to avoid illuminating the sclerotic or the side of the nose. I am not convinced that I have ever seen a hemianopic pupil reaction in a human patient, though I have seen it in a cat after dividing one optic tract. In contrast with Lorain infantilism are cases of achondroplasia, a form of dwarfism due to developmental defect in certain cartilage bones, especially the long bones. Such cases provide most of the Court dwarfs and jesters of history. Their wit and intelligence are normal and they are often strong and agile, and good gymnasts.

A man of 53, of just the same height as the boy, 52 in., has a large head, somewhat resembling the hydrocephalic or even acromegalic type, taking a 7¾ size hat. His limbs are very short, especially the legs, but the trunk is almost normal in development. There is no pituitary or other known glandular defect here, and no affection of vision.

In the early stage of pressure by a pituitary tumour, there is sometimes a paracentral scotoma developed, due to the macular fibres which decussate at the back of the under surface of the chiasma being pressed on. All varieties of visual field defect can be produced by pressure from these tumours. Sometimes the growth escapes through the diaphragma sellæ, and presses upon and may destroy completely one optic tract, causing homonymous hemianopia, or it may press forwards in front of the chiasma and produce partial or complete blindness of one eye only.

A patient who shows such a defect, affecting one eye only, (see Fig. VI.) is aged 65, and only four months ago noticed a defect in his right outer field. This does not seem to have got any worse, according to his own account, but on charting his visual fields I found a defect of the whole of the temporal field of the right eye, both upper and lower quadrants, the nasal field of the right eye and the whole field of the left eye being unaffected. Careful examination showed that there is a broad band of complete blindness in the upper part of the right lower quadrant running inwards to the fixation-point, whereas the upper quadrant and the rest of the lower quadrant can perceive an object, though the illumination is less bright than in the nasal field, and there is complete loss to colour in both quadrants of the temporal field. This is a very unusual distribution of field defect, to find such an extensive loss in the one eye only, with no trace of loss in the opposite eye. It might suggest a lesion of the optic nerve only in front of the chiasma, but X ray photographs (Fig. VII. on Plate) of his skull show great enlargement of the sellar turcica, with erosion of the posterior clinoids, demonstrating the presence of an intrasellar tumour. Nevertheless this patient is in perfect health, so far as he knows; there is no loss of strength, there is no headache, vertigo, nor any general signs of giantism or acromegaly. Yet the X rays show unmistakably the large skull and acromegalic appearance

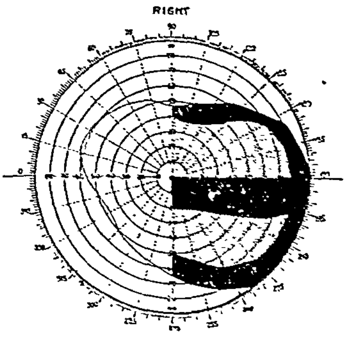

FIG. VI.—Latent acromegaly. Incomplete temporal hemianopia of right eye only. (The radiographic condition is shown in Fig. VII. on Plate.)

of the lower jaw, which is particularly massive, and provide clear evidence of a chromophile excessive activity in the anterior lobe. *The pituitary tumour in this case is probably a mixed type of adenoma, in which the majority of cells are of the neutrophile type, with only slight excess of the internal secretion of the anterior lobe.*

The chromophile and chromophobe types are the two common forms of pituitary adenomata, chromophobe being the more frequent of the two, though owing to the absence of giantism or acromegaly with these tumours, they are less notorious and perhaps less interesting in their general effects. The rarer basophile adenomata do not affect vision.

With regard to the treatment of these sellar tumours, administration of thyroid extract has been used, and some improvement has been observed both as regards the general symptoms and the visual fields, though usually only for a time; but the only certain improvement, or chance of cure, is by operation and the excision of the cyst and of its walls, or of the tumour, if not cystic. Cushing was one of the first to attack these tumours surgically, and he used the intranasal route, decompressing the sella turcica through the sphenoidal sinus. This route has, however, been entirely superseded by the transfrontal method, which is now one of the most satisfactory operations in cerebral surgery. The boy with Lorain infantilism was operated on by Mr. A. Dickson Wright and is making a good recovery, and his papillœdema is already improving, though there is no recovery yet in the temporal fields, and in my experience such recovery is unlikely. In his case papillœdema was commencing as a result of the general increase of intracranial pressure, but in the adult patient of to-day there seems to be no evidence of increase of intracranial pressure. His visual defect is possibly stationary, according to his own account, and he complains of no general symptoms of headache or discomfort, and, as he says himself, his age is 65, all these points being arguments against operative treatment. Should, however, his visual defect be found to increase in intensity, or headache or other symptoms of intracranial pressure develop, the present decision to postpone operation may have to be altered.

Cortical Visual Centres

The visual fibres pass from the optic tracts into nerve-cells in the external geniculate body, thence by a relay by the optic radiations spreading to the visual cortex in the occipital lobe, known as the area striata. Here the fibres end in the grey matter of the cortex almost entirely on the inner aspect of the occipital pole around the calcarine fissure, the area striata reaching forwards almost as far as the junction of the calcarine with the parieto-occipital fissure, and backwards as far as the occipital pole and slightly on the outer side of the lobe. The representation of the areas of the retinæ keep their position in optic nerve, chiasma, tract, radiations, and occipital cortex, so that fibres from the upper halves of the retinæ pass in the dorsum of the chiasma, thence in the dorsal portion of the optic radiations to the lower half of the cuneus and the upper lip of the calcarine fissure. The fibres from the lower halves of the retinæ pass along the under surface of the chiasma, along the ventral portion of the tract and geniculate body to the optic radiations, but here they make a curious bend outwards and forwards into the uncinate region of the temporal lobe, there spreading out over the tip of the descending horn of the lateral ventricle, before turning back along the inferior aspect of the ventricle to reach the inferior lip of the calcarine fissure and the lingual lobe. According to Holmes and Lister [4] and most writers on the subject, the calcarine fissure is the boundary line between the upper and lower quadrants. It is obvious, therefore, that the upper lip of the calcarine fissure and the lower portion of the cuneus is the cortical representation of the lower quadrants of the visual fields, which is by far the more important part of our vision. This area of the cuneus, calcarine fissure, lingual lobe, and occipital pole is known as the area striata, or the visuo-sensory area, and is marked out by the whitish line of Gennari, which corresponds to the optic radiations.

Numerous instances of injury to the occipital lobe, such as gunshot wounds during the war, go to prove that the macula is represented at the tip of the occipital pole, lesions limited to this area causing a paracentral scotoma only, the peripheral portion of the field being unaffected. Furthermore, it would appear that concentric layers forwards of the calcarine area represent concentric areas of the visual fields towards the periphery. There is also evidence that the horizontal levels of the fields are represented in the cortex of the depth of the calcarine fissure, while the vertical bands are represented on the mesial surface of the area striata.[4]

A peripheral area of vision in the field may remain when there is a large paracentral scotoma spreading from the fixation-point out near to the periphery. This would indicate a damage to the occipital pole of the posterior portion of the cuneus and lingual lobe, with some escape of the anterior portion of the visual centre. The curve outwards of the lower portion of the optic radiations into the temporal lobe is the cause of partial hemianopia being sometimes found in association with temporal tumours, careful perimetric fields showing scotomata in the upper quadrants, especially in the nasal field of the eye on the side of the lesion.[5] Owing to the sweep of the dorsal portion of the optic radiations close beneath the parietal cortex, a lesion here is apt to catch these optic radiations and may produce either complete hemianopia or a quadrantic lesion of the lower fields.

Complete destruction of the half vision centre in the occipital area causes total hemianopia, the blind area reaching to the fixation-point, and it seems certain that the macula is not specially bilaterally represented. Partial lesions may cause only partial loss of vision of a hemianopic type, and the grosser forms of vision, such as perception of light and movement, may persist scarcely altered, but the recognition for shape and form may be very deficient, and colour completely lost in the damaged fields. In slighter cases still, shape and form and general illumination may be scarcely affected, though the recognition of colour may be abolished in the blind halves, a hemiachromatopsia. It seems as though the functions of the visual cortex may be divided into light, movement, form, and colour, in progressive order of elaboration, a slight lesion abolishing mainly colour perception, whereas perception of light and movement may persist even with considerable damage. Since colour tests stimulate by only one narrow band of wave length, it is not difficult to understand that a slight lesion of the centre will abolish colour perception, while the coarser stimuli of ordinary light, form, and movement, involving the whole octave of the spectrum, will still evoke responses, though they also are diminished in intensity. For this reason the colour test is much more delicate and easily applied than tests of the field dependent on the recognition of very small white objects, though it is, of course, necessary to be sure that the patient is not congenitally red or green blind. When colour sense is lost, there is probably always some diminution of form sense if a sufficiently small test object is used, such as one measuring 0·3 mm. I find colour testing very useful and rapid in neurological perimetric work, using Gowers' method [6] instead of a perimeter. The test objects I use are two beads, bright red and green, fixed on the ends of a black steel rod about 12 in. in length.

Flicker is an intermittent stimulus, and may be compared to movement of a test object as a stronger stimulus than a stationary object. Anyone who has driven along a road when a low sun is shining through palings across the road will appreciate the intensity of flicker as a stimulus. At high speeds flicker becomes fused to a constant stimulus of steady light. Thus an alternating current supply for electric lighting must have a periodicity of not less than 40 cycles per second, or flicker will become noticeable. The rate of fusion for flicker becomes lowered in lesions of the optic fibres, and tests to determine this rate may be used for comparison of the visual acuity of the quadrantic fields in pituitary lesions, or in other causes of partial hemianopia.

The onset of hemianopia, due to thrombosis of the calcarine artery, may be accompanied by xanthopsia. One of my patients with hyperpiesis developed right hemianopia when in Lincoln cathedral, seeing everything bathed in a golden light for some minutes before her vision failed. Holmes also quotes a case of a woman with occipital lesion, who saw golden crosses and figures.

Word Blindness, Visual Orientation, and Stereoscopic Perception

The angular and supramarginal gyri have definite functions concerned with visual perception and understanding. On the left side of the brain in right-handed people, there is an area called the angular gyrus, whose function is perception and memory retention of written speech, and lesions in this centre may cause inability to read and write. Lesions in the neighbourhood of this centre on the left side may also produce *visual agnosia*, a condition in which objects seen are not recognised until they are handled. The optic radiations run very close beneath this centre, and it is owing to this fact that David Ferrier made the mistake sixty years ago of asserting that this was the cortical centre for vision, as he found that destructive lesions of this centre produced blindness of the opposite eye in animals. It was not until Sharpey Schafer demonstrated that injuries carefully limited to the grey matter in this area did not appreciably affect vision, that it was realised that the blindness produced by Ferrier was due to injury of the closely underlying optic radiations.

Another interesting fact associated with lesions of the optic radiations at this level on the left-hand side is that it produces word-blindness. A localised lesion at this level beneath the cortex, without damaging the actual angular gyrus cortex itself, will produce complete inability to read, though the patient can write freely. Hence we have the curious phenomenon that the patient may write freely and at large, but cannot read a word as soon as he has written it. Such patients always have right hemianopia in addition. This condition, due to a localised vascular lesion, thrombotic or hæmorrhagic, and usually in older persons, is not to be confounded with congenital word-blindness, in which the visual word centre in the angular gyrus does not appear to develop its normal function. Certain school-children have been found who never learned to read, though they may show normal intelligence in other respects.

Bilateral lesions of the supramarginal gyri have been shown to produce apraxia of the limbs, or an inability to perform simple movements, and a disturbance of vision in which the relative sizes and distance of objects is not appreciated, in which the visual attention is poor and orientation faulty, so that a patient thus afflicted has the utmost difficulty in finding his way across a room past simple obstacles such as chairs, even though he sees them quite well. Two cases have been described in which there was complete loss of stereoscopic perception of depth, everything appearing flat and bidimensional.

One case described by Riddoch [7] of a gunshot wound through the left frontal area, the bullet finally coming to rest close to the right calcarine fissure, gave rise to a left hemianopia with incomplete recovery of the lower fields. In addition to considerable sensory loss on his right hand, the patient had complete loss of *stereoscopic* perception of depth, all objects appearing flat and bidimensional, so that he had great difficulty in recognising faces, and he also had loss of visual orientation with complete inability to judge distances.

Riddoch does not explain the condition, but it was clearly not due to any loss of function of the right occipital cortex, as the stereoscopic defect applied to all the undamaged fields. The stereoscopic loss was possibly due to a bilateral lesion of the longitudinal fibres connecting the occipital and frontal lobes, and to an intellectual loss of power of fitting the two half fields together, comparable to apraxia of the hands. Holmes [8] published a similar case amongst his eight cases of loss of visual orientation in supramarginal gyrus lesions.

Visuo-psychic Centre

Irritative lesions of the calcarine area, such as may occur in migraine, or in adhesions of old meningitis, which may set up epileptic seizures, may be preceded by low-grade visual spectra, such as flashing red and green lights, or the fortification spectrum of migraine. It is practically certain, therefore, that irritative lesions of the occipital half-vision centre do not produce the elaborate images of intellectual vision, but that these must be formed elsewhere by redistribution of stimuli from the occipital cortex.[10] Such a visuo-psychic centre may be in the upper portion of the cuneus, the fusiform gyrus,[5] and on the outer side of the occipital cortex, but there is very little definite knowledge, except that electric stimuli to this area will produce movements of the eyes. Without doubt, visuo-psychic perceptions are ultimately concerned with the frontal lobes.

Visual Hallucinations

Visual hallucinations are well-known phenomena in delirium tremens and in other insanities, but are especially liable to occur when there is a lesion of the visual apparatus. This may be anywhere between the eye itself and the area striata in the occipital cortex, and the hallucinations are liable to be referred to the blind fields only when the lesion affects the optic tract, geniculate body, optic radiations, or calcarine cortex. My own view [9] is that high-grade hallucinations cannot possibly be elaborated in the half-vision centre in the calcarine area. This centre, as a sensory centre, no doubt corresponds to Hughlings Jackson's " middle level " of the motor representation of the limbs and trunk, the so-called " motor " area. Low-grade visual sensations, such as red and green lights, or the fortification spectrum of migraine, are probably originated by a discharging lesion in the area striata, such as areas of softening, but complex visual phenomena are probably no more originated there than are complex purposive movements originated in the "motor" limb centres. The visuo-psychic area must have a large share in their production, though such action may be set up reflexly by peripheral irritation of the optic path. For this purpose we may consider the area striata to be part of the periphery, which includes the eye and retina and the whole course of the optic fibres. The peripheral disease merely determines the localisation of the spectral hallucinations which in disease of one eye are referred only to the visual field of that eye, whereas in disease of one optic tract, or of the radiations or the area striata, they are referred to the corresponding half fields.

Numerous cases have been described of visual hallucinations seen in the blind fields in patients suffering from hemianopia, due to various lesions from optic tract to occipital cortex. The visions may be of people or animals, usually in the periphery of vision, standing or moving. In a case of my own[10] following a fit with left-sided convulsions, the patient described very elaborate visions of people in wheel chairs dressed in brilliant garments of green and gold, passing from the left periphery to the midline. In occipital tumours similarly, hallucinations have been described, but more particularly these have been observed in cases of temporal tumour.

In the case of right temporal tumour of Cushing's,[11] with left upper quadrantic field defect, referred to by Horrax,[12] a young man, subject to uncinate attacks, had a recurring visual hallucination on his left side in which he saw his father sitting at a table playing cards, and quarrelling with some other men, the patient always exhibiting signs of fear and horror. Subconscious memory was apparently not responsible for this aura, as he had never seen his parent in such a position, nor did his father ever play cards.

The probability is that here also the visual hallucinations are produced reflexly through irritation of the optic radiations acting through the connexions of the occipital cortex with the visuo-psychic and frontal centres.

Transient Hemianopia and Macular Centre

Temporary exhaustion paralysis of the half-vision centre on one side may occur, and does occur commonly in migraine possibly due to vaso-motor spasm of the calcarine branches of the posterior cerebral arteries causing temporary anæmia of this area. Temporary hemianopia is a common symptom in many cases of migraine, and it may be associated with the low-grade visual aura known as the scotoma scintillans, or fortification spectrum. Very occasionally this hemianopia has been known to remain permanent, possibly due to non-dilatation and thrombosis of the calcarine vessel following the primary spasm in the artery.

A similar exhaustion paralysis of the half-vision centre may be produced by an irritative discharging focus, as a cyst or area of softening, in the neighbourhood, as in the precuneus or quadrate lobe, when epileptic fits may be succeeded by complete hemianopia lasting perhaps 24 hours. In such cases, if examined fairly early, it will be found that the hemianopia is absolute, a bright flame not being seen until it reaches the fixation-point. All these cases of hemianopia when they clear up, clear up from the centre towards the periphery. A point over which there has been much controversy in the past is the representation of the macula in the cortex, and it has been suggested that the whole of it is bilaterally represented. I proved many years ago, in 1897,[6] that exhaustion hemianopias are absolute up to the middle line and fixation-point, and the numerous cases of war wounds damaging the occipital cortex have gone further to prove that there is no special bilateral representation of the macula. Yet numerous cases show hemianopia fairly complete up the middle line, except for the exclusion of a small area leaving the fixation-point in the seeing field. This is probably due to the fact that the macula is represented at the occipital pole and slightly on the outer side on the occipital cortex close to the junction of the arterial supply where the middle cerebral and posterior cerebral vessels meet, and the escape of the macular area is probably due to an alternate supply thus reaching it from the terminations of the middle cerebral vessels.

A man, aged 70, was attacked by severe headache and gross disturbance of vision. When admitted to hospital he was found to have complete left hemianopia and no other abnormal symptoms. The blindness of the left half fields was still absolute three weeks after the onset. The lesion was probably a thrombosis of the calcarine branch of the posterior cerebral artery, and it is quite probable that if he were to be tested carefully six or twelve months later, it would be found that a small area around the fixation-point would then be included in the seeing half field, due to partial recovery of the macular centre at the occipital pole, owing to the alternative blood-supply.

Double Hemianopia

A bilateral lesion, therefore, of the occipital cortex, if it is not destructive, such as by gunshot wound, but due to cerebral thrombosis, will show at first complete blindness, a double hemianopia, with subsequent recovery of a small area of central vision of about 5° around the fixation-point, resembling in appearance the well-known pin-point fields of hysteria. The vision differs from that of the hysteric in that in the organic case there is very marked loss of power of orientation, as the loss of peripheral vision is real and not psychical; in them there is no visual reflex from the periphery, and consequently the patient is much disturbed with regard to his own position and the position of objects in space. His vision may in fact be compared to that of a normal individual looking through two parallel tubes held close up against each eye.

UNIVERSITY COLLEGE HOSPITAL.—The Duke of Kent, president of the hospital, was in the chair at the centenary banquet held at the Guildhall on May 2nd in support of the appeal for £250,000 to provide a new pay-bed hospital and nurses' home, and for extensions to the antenatal and infant welfare departments. In replying to the toast of the hospital, proposed by the Duke, Sir Herbert Samuelson, chairman and treasurer, said that of late years they had concentrated on antenatal and child welfare work, and they could boast that they never lost sight of a child born within their portals until he had attained the age of twelve. Donations amounting to £22,882 have been received, including £1000 from the Duke's wedding fund and £7500 from Sir H. Samuelson.

ÆTIOLOGY OF ACUTE RHEUMATISM

EXPERIMENTAL EVIDENCE OF A VIRUS AS THE CAUSAL AGENT

By Bernard Schlesinger, M.D. Camb., F.R.C.P. Lond.[*]
PHYSICIAN TO OUT-PATIENTS, HOSPITAL FOR SICK CHILDREN, GREAT ORMOND-STREET, LONDON

A. Gordon Signy, M.B. Lond.[*]
ASSISTANT PATHOLOGIST AND RESEARCH FELLOW AT THE HOSPITAL; AND

RESEARCH FELLOW IN BACTERIOLOGY, LISTER INSTITUTE, LONDON

WITH A NOTE ON PHOTOMICROGRAPHS ON SPECIAL PLATE
by J. E. Barnard, F.R.S.

The view that rheumatic fever is of microbic origin was first formulated in the later part of the nineteenth century. Following Mantle's description in 1887 of a diplococcus that he had isolated from the blood of patients with acute rheumatism many reports concerning the bacteriology of the disease were published. The belief that streptococci are ætiologically related to the disease was mainly founded on the work of Triboulet and Apert in 1898, and on that of Westphal, Wassermann, and Malkoff in 1899. In this country the researches of Poynton and Paine in 1900 were the first to awaken interest in the bacteriology of the rheumatic disease. Their conclusions gave rise to a lengthy and world-wide controversy which has continued to the present day. Although it is now universally recognised that hæmolytic streptococci play an important part in the ætiology, the evidence that has accumulated during the past 35 years still fails to provide conclusive evidence that these organisms represent the causal agent. It is unnecessary to review here the extensive literature on which this statement is based. Detailed critical reviews by Wright (1929) and Gibson and Thomson (1933), which include a consideration of the allergic theories advanced by some modern writers, are readily available, and to these the reader is referred. It therefore appears to be fair to state that the cause of rheumatic disease is still not definitely known.

The demonstration of a virus as the causal agent of acute rheumatism has been attempted by several investigators.

De Vecchi (1912) reported the production of a myocarditis which he regarded as similar to that of rheumatic fever by the inoculation into rabbits, dogs, rats, and mice of bacteria-free blood obtained from patients suffering from rheumatic fever. These observations were partially confirmed by Natali (1923). Attempts by Miller (1924) to repeat the experiments recorded by these workers were unsuccessful. Rabbits and guinea-pigs were inoculated with whole blood, serum, joint fluid, pleural exudate, throat washings, and suspensions of tonsillar tissue. The inocula were in every case bacteriologically sterile. Out of a total of 107 animals inoculated 2 developed an acute non-bacterial arthritis. In about half the rabbits and two-thirds of the guinea-pigs myocardial lesions were encountered which consisted of interstitial accumulations of lymphocytes and endothelial cells. Similar lesions, however, were observed in control animals, and it was therefore concluded that the experiments described by the Italian workers were inconclusive. Gross, Loewe, and Eliasoph (1929) have reported an extensive series of somewhat similar experiments in which seven different species of animals were tested. The results were entirely negative.

These unsuccessful experiments do not necessarily imply that a virus is not the cause of rheumatism; they merely show that the animals tested are not susceptible to inoculation. As is well known, quite a number of virus diseases have not yet been successfully transmitted to species other than that of the natural host, though some remarkable advances have been made in this direction in recent years.

In The Lancet last week (Schlesinger, Signy, and Payne, 1935) it was suggested that the infection with hæmolytic streptococci, by producing a condition of increased tissue susceptibility, enabled some as yet undiscovered causal agent to enter the body, or allowed such an agent already lying latent in the body to assume active characters. It was further suggested that this causal agent might be of the nature of a virus. In the present paper the results of an attempt to obtain experimental evidence in favour of this hypothesis are recorded.

One of us, B. S., was responsible for the clinical part, and A. G. S. for the clinical pathology of the investigation now to be described. The examination of rheumatic exudates and the agglutination tests with the antigens obtained from these were performed at the Lister Institute by C. R. A., who is alone responsible for this part of the work.

Methods Employed

It has already been mentioned that the results of inoculating animals with rheumatic joint fluids, &c., have been unsatisfactory. It seemed desirable therefore to employ a technique whereby a preliminary concentration of the causal agent could be obtained. One possible method of doing this was to submit rheumatic exudates or suspensions of infected tissues to high-speed centrifugation in the hope that the agent would be deposited in the sediment so obtained. The high-speed centrifuge has been used successfully for this purpose in the study of several virus diseases, including vaccinia (Eagles and Ledingham, 1932), psittacosis (Bedson, 1933), trachoma (Thygeson, 1934), varicella and zoster (Amies, 1933, 1934). Only those virus agents of which the infective particles are relatively large (100–200 mμ) are susceptible to the degree of centrifugal force developed by the high-speed machines at present available. It was realised therefore that this method would only be successful if the rheumatic agent were of this order of size.

Search for Elementary Bodies in Rheumatic Exudates

It seemed reasonable to assume that the most active and extensive inflammatory lesions would contain the causal agent in greatest amount. For this reason, the majority of the cases chosen for study were examples of very acute infections that had rapidly progressed to a fatal termination. In 4 of the 7 cases examined, the duration of the pericarditis had been under five weeks. At the post-mortem examination each of these revealed a pericarditis with the typical "bread and butter" appearance. In one case death had occurred rapidly from acute carditis and, although a pericardial effusion was found, there was no evidence that the pericardium itself was involved. Histological examination showed widespread collections of Aschoff nodes throughout the myocardium and cardiac valves, and also in other areas of the body. In the three remaining cases the pericarditis was of a more chronic character, and firmer adhesions or almost total obliteration of the pericardium were encountered at autopsy. Pneumonia of the type that many authorities now recognise as specific in rheumatism was present in 6 of these 7 cases.

---

[*] Working with a grant from the Harmsworth Fund.

The pericardial fluid was removed with aseptic technique within twelve hours of death.

After carefully sterilising the skin over the precordium a needle was inserted in the second left intercostal space close to the sternum, with the cadaver in a propped-up position. The fluid was then withdrawn with a syringe and transferred to a tube containing a few cubic centimetres of a 3·8 per cent. solution of sodium citrate. In three cases in which there were extensive pericardial adhesions this method proved unsuccessful, and the fluid was then obtained after the thorax had been opened, the surface of the pericardium being sterilised with a searing iron before insertion of the needle.

Samples of pleural fluid, if present, were obtained in the same manner. Each specimen was tested for sterility by cultivation in 10 per cent. serum broth for 72 hours. The pericardial fluids proved to be sterile in every case.

The pericardial fluid thus obtained was then submitted to a process of fractional centrifugation similar to that employed for obtaining elementary body suspensions from varicella and zoster vesicle fluids (Amies, 1934). The exudate was first centrifuged for 20 minutes at 2000 revolutions per minute to remove cell debris. The clear supernatant fluid was transferred to fresh tubes and again centrifuged at a speed of 12,000–14,000 r.p.m. for 30 minutes. This yielded a small deposit, just visible to the naked eye. The supernatant fluid was removed and discarded, and the sediment was rubbed off the bottom of the tube with a glass rod, resuspended in physiological saline and again deposited by means of the high-speed centrifuge. Finally, the washed deposit was suspended in physiological saline containing 0·25 per cent. of formalin and centrifuged lightly to remove any imperfectly dispersed material. The suspension thus prepared had a bluish opalescent appearance and showed no tendency to spontaneous flocculation.

MICROSCOPIC EXAMINATION OF SUSPENSIONS

When a drop of the suspension was examined under the microscope, using the dark-ground method of illumination and a magnification of 1000 diameters, it was found to contain numberless small particles. This, of course, was to be expected. Slight differences in the size and refractility of these particles was observed, and it was recognised that many of them were probably minute fragments of cell protoplasm such as occur in any pathological fluid. In addition to these, however, there were other particles of uniform size which, in the light of previous experiences with other virus diseases, appeared closely to resemble elementary bodies. Several methods of preparing stained films of these suspensions were tried. Loeffler's method of staining flagella and the modified techniques of Zettnow and Cassares-Gil gave satisfactory results. In such preparations it was again possible to identify particles of uniform size. In the case of one of the pericardial fluids examined it was possible by repeated fractional centrifugation to obtain an almost pure suspension of these bodies whose appearance, both under dark-ground illumination and in stained preparations, was quite definite.

Pleural exudates were present in 5 of these 7 cases. Four of these were submitted to high-speed centrifugation, and numerous bodies similar to those found in the pericardial fluids were recognised in one of the deposits so obtained. Details of the seven cases examined with the results obtained in each are given in Table I.

In order to provide adequate controls for this investigation 8 pericardial exudates and 2 pleural exudates obtained from non-rheumatic conditions were centrifuged at high speed in exactly the same manner as that described above. These control fluids yielded small deposits from which fairly stable suspensions could be prepared. These also showed large numbers of particles of varying size and refractility, but the bodies of uniform size and characteristic appearance seen in the rheumatic pericarditis suspensions were absent.

PHOTOMICROGRAPHY

Note by J. E. BARNARD

The photomicrographs accompanying this paper are of material supplied by the authors.

FIG. I.—Agglutinated suspension in hanging drop under ordinary dark-ground illumination. Objective used 16 mm. apochromat. (× 70.) Transmitted light.

FIG. II.—Agglutinated suspension mounted on quartz slide and somewhat compressed between slide and cover-glass to show the probable virus bodies immersed in a granular matrix. The photomicrograph was taken in ultra-violet light by the dark-ground method devised at the National Institute for Medical Research. It will be seen that the probable virus bodies have a different refractive index in the wave-length used to that of the matrix; the latter is substantially less visible. This difference is detectable in visible light if a high aperture dark-ground illumination method is used, but it would be difficult and perhaps impossible to obtain satisfactory photomicrographs under those conditions. Objective used 1·7 mm. quartz monochromat. with an effective N.A. of 2·5 in the wave-length used. (× 1000.)

FIG. III.—Unagglutinated suspension of centrifuged deposit. The method adopted was substantially the same as that described in the identification of virus bodies in infectious ectromelia (Barnard, 1932). As only one sample was available for photography no claim is made that anything like a conclusive result has been obtained, but it is suggestive. The deposit apparently consists of virus bodies with a considerable proportion of tissue debris. The suggestion that some at least are virus is dependent on regularity of size and constancy of refractive index in all wave-lengths that have been used. Further, single bodies are seen which are elongated and suggest that transverse binary fission is taking place. The size of the virus can hardly exceed 100 mμ and may be as small as 80 mμ, but the latter dimension is difficult to determine with any accuracy unless photomicrographs are taken in a shorter wave-length than that used. (× 3200.)

FIG. IV.—Streptococcus photographed under similar conditions as Fig. III. and at exactly the same magnification for purposes of comparison.

These control fluids yielded small deposits from which fairly stable suspensions could be prepared. These also showed large numbers of particles of varying size and refractility, but the bodies of uniform size and characteristic appearance seen in the rheumatic pericarditis suspensions were absent.

PHOTOMICROGRAPHY

Note by J. E. BARNARD

The photomicrographs accompanying this paper are of material supplied by the authors.

FIG. I.—Agglutinated suspension in hanging drop under ordinary dark-ground illumination. Objective used 16 mm. apochromat. (× 70.) Transmitted light.

FIG. II.—Agglutinated suspension mounted on quartz slide and somewhat compressed between slide and cover-glass to show the probable virus bodies immersed in a granular matrix. The photomicrograph was taken in ultra-violet light by the dark-ground method devised at the National Institute for Medical Research. It will be seen that the probable virus bodies have a different refractive index in the wave-length used to that of the matrix; the latter is substantially less visible. This difference is detectable in visible light if a high aperture dark-ground illumination method is used, but it would be difficult and perhaps impossible to obtain satisfactory photomicrographs under those conditions. Objective used 1·7 mm. quartz monochromat. with an effective N.A. of 2·5 in the wave-length used. (× 1000.)

FIG. III.—Unagglutinated suspension of centrifuged deposit. The method adopted was substantially the same as that described in the identification of virus bodies in infectious ectromelia (Barnard, 1932). As only one sample was available for photography no claim is made that anything like a conclusive result has been obtained, but it is suggestive. The deposit apparently consists of virus bodies with a considerable proportion of tissue debris. The suggestion that some at least are virus is dependent on regularity of size and constancy of refractive index in all wave-lengths that have been used. Further, single bodies are seen which are elongated and suggest that transverse binary fission is taking place. The size of the virus can hardly exceed 100 mμ and may be as small as 80 mμ, but the latter dimension is difficult to determine with any accuracy unless photomicrographs are taken in a shorter wave-length than that u (× 3200.)

FIG. IV.—Streptococcus photographed under similar conditions as Fig. III. and at exactly the same magnification for purposes of comparison.

No attempt was made to measure the size of these particles since the methods commonly employed for this purpose (ultrafiltration and ultracentrifugation) require the use of a susceptible laboratory animal. It is sufficient, therefore, to state that the bodies found in suspensions obtained from rheumatic pericardial fluid were distinctly smaller than vaccinia elementary bodies when examined under the same optical conditions. It is fully realised that the utmost caution must be used in interpreting the results of microscopical examinations of this kind. We believe, however, that these findings can be regarded as significant when taken in conjunction with the other experimental evidence now to be described.

TABLE I

Case.	Clinical condition—			Duration of illness.	Elementary bodies in fluids from—	
	Pericarditis.	Carditis.	Pneumonia.		Pericardium.	Pleura.
1	Acute.	+	+	2 weeks.	+	No effusion.

7	Chronic.	+	+	Several months.	0	0

Except in Case 4 post-mortem examinations were performed and the clinical condition was thereby confirmed.

Agglutination of Suspensions Obtained from Pericardial Exudates

It has already been shown in a number of virus diseases that elementary bodies which on other grounds are regarded as the causal agents are specifically agglutinated by the corresponding antisera. This phenomenon was first described by Ledingham (1931) in the case of vaccinia and fowl-pox, and has since been demonstrated in varicella and zoster (Paschen, 1933; Amies, 1933). Such agglutination reactions provide additional evidence in favour of the view that elementary bodies represent the actual infective agents, and at the same time they form a useful method for studying the development of immunity to the virus in question. The application of this method of investigation to the present problem was obviously indicated. The results of preliminary experiments were encouraging and the method has now been given a fairly extensive trial.

The technique of preparing the suspensions has already been described. Owing to the small amount of antigen available it was necessary to employ a microscopic method of carrying out the agglutination tests.

Mixtures consisting of equal volumes of the antigen suspension and an appropriate dilution of the serum to be tested were set up as hanging drops, using an aluminium ring moist chamber in preference to a hollow-ground slide which is too shallow for this purpose. Each serum was usually tested in a series of falling dilutions from 1 in 4 to 1 in 128. Controls consisting of antigen with normal serum and antigen with saline were included in each test. The preparations were allowed to remain at room temperature (average 65° F.) and examined after 24, 48, and 72 hours. At these intervals the preparations were examined microscopically with transmitted light, using a 16 mm. objective and a ×10 ocular. A positive reaction was indicated by the appearance of small, irregularly shaped, highly refractile floccules. These were usually visible 24 hours after setting up the tests, but their appearance was sometimes delayed to 48 hours. The control preparations, consisting of antigen and normal serum or saline, appeared perfectly clear when examined under the same conditions.

In order to determine the nature of these floccules the hanging drop was transferred to a clean slide and examined by dark-ground illumination. It was then evident that the floccules consisted of aggregates of the small bodies of uniform size already identified in the pericardial suspensions.

RESULTS OBTAINED

The agglutination reaction as described above has been carried out on the sera obtained from 36 patients suffering from rheumatic disease, all of whom showed well established cardiac involvement. The series included acute, convalescent, and quiescent cases. A clear definition of these terms is necessary, since the results obtained with the agglutination test were found to depend on the degree of activity of the rheumatic process. An *active* infection was recognised by the presence of two or more of the following: pyrexia, tachycardia, extension of the cardiac signs, the presence of subcutaneous nodules, and failure to gain in weight. Significance was also attached to an increased erythrocyte sedimentation-rate, and no case was considered to be free from active rheumatism until the sedimentation-rate had fallen to a normal figure. Patients were regarded as *convalescent* when they had recently passed through a stage of acute rheumatism while under our personal supervision. In some of these patients, pericarditis, subcutaneous nodules, and arthritis had been present during the acute phase, while in others the presence

No attempt was made to measure the size of these particles since the methods commonly employed for this purpose (ultrafiltration and ultracentrifugation) require the use of a susceptible laboratory animal. It is sufficient, therefore, to state that the bodies found in suspensions obtained from rheumatic pericardial fluid were distinctly smaller than vaccinia elementary bodies when examined under the same optical conditions. It is fully realised that the utmost caution must be used in interpreting the results of microscopical examinations of this kind. We believe, however, that these findings can be regarded as significant when taken in conjunction with the other experimental evidence now to be described.

TABLE I

Case.	Clinical condition—			Duration of illness.	Elementary bodies in fluids from—	
	Pericarditis.	Carditis.	Pneumonia.		Pericardium.	Pleura.
1	Acute.	+	+	2 weeks.	+	No effusion.
2	None.	+	+	3 ,,	+	Contaminated.

Except in Case 4 post-mortem examinations were performed and the clinical condition was thereby confirmed.

Agglutination of Suspensions Obtained from Pericardial Exudates

It has already been shown in a number of virus diseases that elementary bodies which on other grounds are regarded as the causal agents are specifically agglutinated by the corresponding antisera. This phenomenon was first described by Ledingham (1931) in the case of vaccinia and fowl-pox, and has since been demonstrated in varicella and zoster (Paschen, 1933; Amies, 1933). Such agglutination reactions provide additional evidence in favour of the view that elementary bodies represent the actual infective agents, and at the same time they form a useful method for studying the development of immunity to the virus in question. The application of this method of investigation to the present problem was obviously indicated. The results of preliminary experiments were encouraging and the method has now been given a fairly extensive trial.

The technique of preparing the suspensions has already been described. Owing to the small amount of antigen available it was necessary to employ a microscopic method of carrying out the agglutination tests.

Mixtures consisting of equal volumes of the antigen suspension and an appropriate dilution of the serum to be tested were set up as hanging drops, using an aluminium ring moist chamber in preference to a hollow-ground slide which is too shallow for this purpose. Each serum was usually tested in a series of falling dilutions from 1 in 4 to 1 in 128. Controls consisting of antigen with normal serum and antigen with saline were included in each test. The preparations were allowed to remain at room temperature (average 65° F.) and examined after 24, 48, and 72 hours. At these intervals the preparations were examined microscopically with transmitted light, using a 16 mm. objective and a ×10 ocular. A positive reaction was indicated by the appearance of small, irregularly shaped, highly refractile floccules. These were usually visible 24 hours after setting up the tests, but their appearance was sometimes delayed to 48 hours. The control preparations, consisting of antigen and normal serum or saline, appeared perfectly clear when examined under the same conditions.

In order to determine the nature of these floccules the hanging drop was transferred to a clean slide and examined by dark-ground illumination. It was then evident that the floccules consisted of aggregates of the small bodies of uniform size already identified in the pericardial suspensions.

RESULTS OBTAINED

The agglutination reaction as described above has been carried out on the sera obtained from 36 patients suffering from rheumatic disease, all of whom showed well established cardiac involvement. The series included acute, convalescent, and quiescent cases. A clear definition of these terms is necessary, since the results obtained with the agglutination test were found to depend on the degree of activity of the rheumatic process. An *active* infection was recognised by the presence of two or more of the following: pyrexia, tachycardia, extension of the cardiac signs, the presence of subcutaneous nodules, and failure to gain in weight. Significance was also attached to an increased erythrocyte sedimentation-rate, and no case was considered to be free from active rheumatism until the sedimentation-rate had fallen to a normal figure. Patients were regarded as *convalescent* when they had recently passed through a stage of acute rheumatism while under our personal supervision. In some of these patients, pericarditis, subcutaneous nodules, and arthritis had been present during the acute phase, while in others the presence

The number assigned to the suspension corresponds to that of the case from which it was prepared. (See Table I.)

of an active infection was recognised by a combination of the signs and symptoms enumerated above. In this group of convalescent cases the blood was examined four to eight weeks after the cessation of the stage of activity. The group of *quiescent* cases consisted of patients in whom no signs of active rheumatic infection had been observed for many months. The results obtained are summarised in Table II.

From the results shown in Table II., it is evident that agglutinins could be demonstrated only at certain stages of the disease. The highest titres were obtained with the sera of patients in whom the rheumatic process had been active for a long period. Multiple subcutaneous nodules, indicating a wide dissemination of the infective agent, were a characteristic feature of the clinical picture presented by these patients. Even when relapses occurred and the infection developed into an acute pericarditis or pleurisy, as in Cases 1 and 3, the production of agglutinins was maintained. When, on the other hand, the disease steadily progressed to a fatal termination, possibly owing to a poor resistance on the part of the patient or as the result of a particularly virulent infection, the tests for specific agglutinins were negative. Positive reactions were only obtained in 2 out of 10 patients who were in the early stages of convalescence from active rheumatism and in only 2 out of 16 quiescent cases.

CONTROL EXPERIMENTS

During the course of the investigation each antigen was tested against a number of sera obtained from normal healthy persons and from patients suffering from various non-rheumatic diseases. Completely negative reactions were obtained with sera from the following conditions: 9 cases of syphilis (6 with a positive Wassermann reaction); 12 cases of zoster, all of which agglutinated a zoster elementary body suspension; 2 cases of active rheumatoid arthritis; 4 cases of active Still's disease; and 2 cases of streptococcal tonsillitis (taken 2 weeks after the attack).

As previously mentioned suspensions were prepared from pericardial and pleural fluids of non-rheumatic control cases. With none of these was a positive agglutination obtained with any of our known agglutinating sera.

The possible influence of hæmolytic streptococcal throat infections on the agglutination reaction was further investigated by testing 6 sera obtained from patients who were convalescent from scarlet fever. The blood was taken approximately three weeks after the onset of the disease. In 5 of these, there was no history of rheumatic disease and the sera failed to agglutinate the rheumatic pericarditis suspensions. In one case, however, the agglutination reaction was positive. When the patient was examined it was found that there had been persistent tachycardia during the third week of convalescence and that the temperature was slightly raised (99·6° F.) on the day on which the blood sample was taken. There was no evidence of cardiac disease, but the patient gave a definite history of "joint pains" and it was found that her mother suffered from mitral stenosis.

The following experiment also shows that streptococcal antibodies play no part in the agglutination reaction here described. Thirteen sera obtained from patients in various stages of rheumatic disease were tested for antistreptococcal agglutinins, using a suspension of hæmolytic streptococci ("Carter" strain) as antigen. Of these 13 sera, 2 agglutinated this suspension to a titre of 1 in 8, while the rest gave completely negative reactions. The same 13 sera were then tested with a rheumatic pericardial suspension. The 2 sera that contained antistreptococcal agglutinins gave a negative reaction, while a positive result was obtained with 4 other sera in which antibodies for streptococci had not been demonstrated.

It has already been mentioned that an increased erythrocyte sedimentation-rate was constantly present in those cases of active rheumatism in which a positive agglutination reaction was obtained. Increased velocity of sedimentation of the red blood-cells depends largely upon an increase of serum globulin and fibrinogen, and it therefore appeared necessary to exclude the possibility that such alterations in the blood protein content were responsible for flocculation of the antigen. For this purpose 5 sera obtained from women in the late stages of pregnancy were each tested against three different pericardial suspensions. The results were entirely negative.

It was also necessary to consider one further possible source of error. Since the human isoagglutinogens can be demonstrated not only in the erythrocytes and fixed tissue cells but also in saliva and urine (Yamakami, 1926), it was thought that they might possibly also be present in pericardial exudates. If this were so, the antigens prepared from pericardial fluids might contain these agglutinogens which would then react with the corresponding isoagglutinins, should these be present in the serum to be tested. Fortunately this serological complication did not occur in actual practice; examples of it would otherwise have been encountered among the control tests. This conclusion was confirmed by ascertaining the blood groups of 12 rheumatic patients whose sera had already been tested for agglutinins, the same sample of antigen being employed in each case. No correlation between the two reactions was found.

Discussion

The investigations described in this paper, although by no means exhaustive, are regarded by us as definite evidence in favour of the hypothesis that the infective agent of rheumatic disease is a virus. The striking similarity between the results obtained in the present study and those reported in connexion with such established virus infections as varicella and vaccinia-variola with regard to the isolation of elementary bodies and the agglutination of these by the homologous antiserum, lends considerable support to this belief. The final proof, however, must rest upon the demonstration that the bodies described in this investigation are capable of reproducing the disease in a susceptible animal. The number of viruses that have been successfully adapted to a foreign host is steadily increasing and further attempts to achieve this object in the case of rheumatic disease are indicated.

This new conception of the ætiology appears to offer an explanation of several facts in the pathogenesis of the disease which the older theories cannot account for. Acute rheumatism has long been recognised as a disease that shows a special affinity for certain tissues such as the endothelial lining of the heart, the blood-vessels, serous membranes, and connective tissue throughout the body. Furthermore, the submiliary nodule which is the fundamental basic lesion and represents the essential reaction of the tissues to the infective agent is characterised by an active proliferation of cells derived from the reticulo-endothelial system. A similar type of inflammatory lesion is equally characteristic of vaccinia, for Ledingham (1924) and others have shown that this virus proliferates in tissues of mesoblastic origin and that the reticulo-endothelial tissue is the seat of primary attack and takes the chief share in repair.

The pulmonary manifestations of acute rheumatism are also of interest in this connexion. Naish (1928) and many others have stated that the changes which are sometimes present in the lungs are peculiar to rheumatism and quite unlike those found in the usual type of pneumococcal pneumonia. The hæmorrhagic character of the inflammation, with much proliferation of endothelial cells, thickening of the alveolar walls, and absence of much fibrin and polymorphonuclear cells, bears a striking resemblance to the condition found in influenzal pneumonia in man, and also to the pulmonary changes in swine influenza. We believe, in conclusion, that the evidence obtainable from a histological study of rheumatic lesions is more in accordance with the conception of a virus as the ætiological agent than with any other theory.

The characteristic properties of the infective agent of rheumatism cannot be closely paralleled with those of any known virus. Some of its characters, however, are shared by a number of virus agents. Such diseases as variola and mumps which run an acute course and confer a solid immunity to reinfection clearly have nothing in common with acute rheumatism. There are other virus diseases, however, such as herpes febrilis, in which the agent remains in the tissues for long periods and becomes manifest only when the general powers of resistance to infection are lowered. In this case the period of immunity following a clinical attack is comparatively short and the infective agent can be demonstrated in the nasopharyngeal secretion in the intervals between attacks.

Many other questions relating to the epidemiology of rheumatic disease, such as the significance of subclinical infections and the possibility of a true symbiotic relationship between the virus of rheumatism and hæmolytic streptococci, could be discussed in the light of this new conception of the ætiology. Such discussion, however, would be mainly speculative. We prefer, therefore, to confine ourselves at present to a simple record of the experimental findings in the hope that further research along these lines will eventually solve the problem of the causation of rheumatic disease.

Summary

1. The deposits obtained by high-speed centrifugation of pericardial fluid from cases of acute rheumatic pericarditis contain particles which morphologically resemble virus elementary bodies. Similar bodies have been found in the deposit obtained from one pleural exudate in association with rheumatic pneumonia.

2. Relatively pure suspensions of these bodies in formol saline have been prepared. These suspensions are specifically agglutinated by the sera of patients who are suffering from, and successfully resisting, an acute rheumatic infection. The sera of patients in whom the infection is quiescent fail as a rule to agglutinate these suspensions. Completely negative reactions were also obtained with the serum of normal persons and of patients suffering from various non-rheumatic infections.

3. On the evidence above summarised it is suggested that the bodies found in pericardial exudates represent the actual infective agent of acute rheumatism.

4. The importance of streptococcal infection as a factor in the ætiology of the disease is recognised. It is suggested that the lowered resistance produced by such infections enables the virus to enter the body or, if the virus is already lying latent in the tissues, allows it to assume active characters.

We wish to thank the medical staffs of several hospitals for placing their clinical material at our disposal. We are also grateful to Prof. J. C. G. Ledingham, director of the Lister Institute, and to Dr. David Nabarro, director of the pathological department of the Hospital for Sick Children, Great Ormond-street, for the help they have afforded us throughout this investigation.

THE RELATIONSHIP BETWEEN ADENOMATA AND CANCER OF THE LARGE BOWEL*

By J. P. LOCKHART-MUMMERY, M.B., B.Chir. Camb., F.R.C.S. Eng.

EMERITUS SURGEON TO ST. MARK'S HOSPITAL FOR DISEASES OF THE BOWEL, LONDON

IT has been known for many years that there is a close relationship between so-called innocent adenomatous tumours and cancer, and that an adenoma which is at first innocent may be found at a later stage to have been replaced by cancer. Not infrequently careful microscopical examination of large adenomatous tumours by serial sections has shown that at one part of the tumour invasion of the deep tissues has taken place and malignant change occurred. This was pointed out by Dr. Cuthbert Dukes in 1926 [1] and by him and myself again in 1928.[2] While most of the observations have been made in connexion with adenomata of the large bowel, the same has been shown to be true of duct adenoma of the breast by Sir Lenthal Cheatle [3] and of adenoma of the stomach by Prof. Stewart.[4]

It seemed to me that valuable information might be obtained if the after-histories of a large number of cases of so-called simple adenomata of the large bowel could be traced during a number of years to see exactly what happened to the patients. It is very generally assumed that if an adenoma is removed adequately, and is found on microscopical examination exhibit no evidence of malignant change in any t of its structure, that nothing further is to be ed, and that the patient is cured in the true sense. no real evidence has hitherto been available on ch to base such an assumption, and as I shall to show, it is as a matter of fact quite unjustified false. The patient is by no means certainly cured the removal of the adenoma, however completely removal is carried out. It is probably true that particular adenoma which has been removed will return, but the changes in the epithelial cells which e resulted in the formation of the adenomatous our may still be present and other adenomatous ours are liable to form in the neighbouring helium.

---

* A post-graduate lecture delivered at St. Mark's Hospital on Feb. 4th.

THE INQUIRY

decided to attempt to trace the after-history of a e number of cases of simple, so-called innocent, nomata of the rectum and colon, and to see what portion of recurrences there were, and in what ations they occurred after, what is generally sidered, adequate surgical procedures. Fortunately many years I have made it a habit to examine all es where a simple adenoma has been removed n the bowel at periodic intervals, both in hospital private practice. It has thus been possible to dy the after-history of 50 cases.

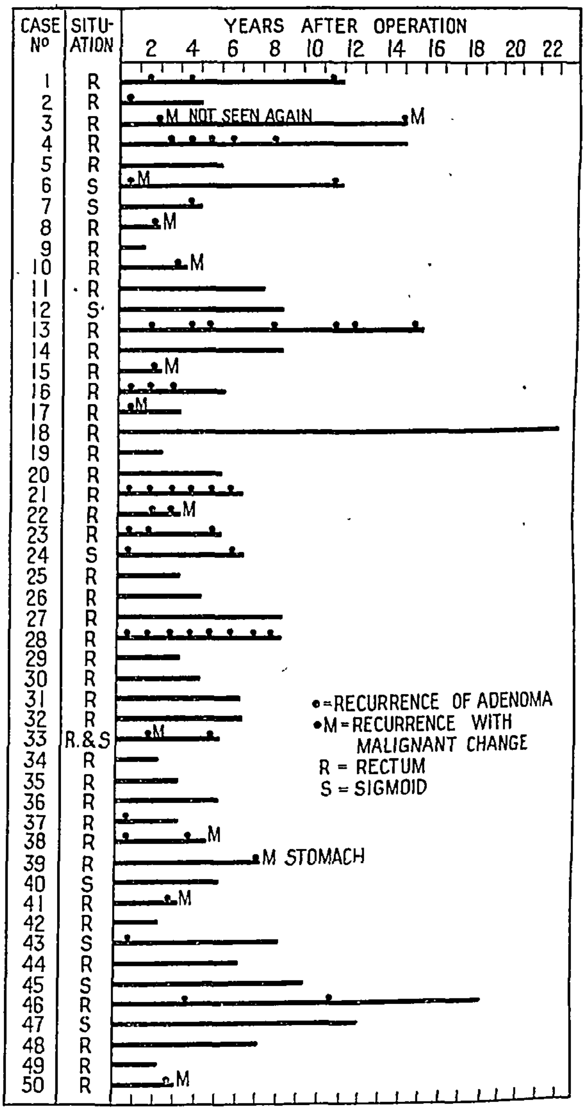
'or the purpose of this investigation I considered iser to leave out entirely all cases of that curious ease adenomatosis, or multiple adenomata, where re are numerous tumours more or less throughout whole colon, as adenomatosis has already been y thoroughly studied and appears to be a disease irely of genetic origin, and although in the present te of our knowledge it is not possible to draw any y hard-and-fast distinction between cases of gle adenomata and cases of adenomatosis, I feel t to mix all the cases together would not be helpful. erefore, all cases of adenomatosis have been entirely luded. Only those cases have been taken in which original adenoma was adequately removed according to our modern standards by some surgical cedure, and where it has been possible to trace the penings for at least a year afterwards.

'he method of removing the adenomata has varied siderably. In those cases where the tumour has sented itself as a pedunculated polyp it has been oved by a wire diathermy snare, or by ligating pedicle when this was possible. When the tumour been large and sessile, it has been cut out with an inch or more margin of healthy mucous nbrane, either through the rectum or from behind er removing the coccyx and the wound in the rectum ored by stitching. In a few cases a local resection performed and in some cases where the tumour very large the rectum has been entirely excised he usual methods. In all cases the original adenoma been properly examined histologically after oval, generally by a series of sections, and its racter as an innocent adenoma verified.

Iost of the cases have been examined sigmoidopically at regular intervals, many of them every months, for a number of years after the original ration, and the findings have been most carefully cked both clinically and pathologically. Some ients have, of course, refused to return for periodic mination, or have been unable to do so, but in a nber of cases which have not returned the subsent history has been obtained from the patient's lical adviser.

)ut of the total of 50 cases there were 25 in which ther tumour developed, and 12 where malignant nours, adenocarcinoma, subsequently developed. In 25 cases there was no recurrence of any kind. In 13 cases other adenomata developed more than once in different sites. The average age of the patients was about 60. One of the cases counted among the recurrences is a patient who developed a cancer of the stomach seven years after removal of the original adenoma.

Some of the cases were very remarkable. Thus, one patient had no less than eight adenomata in different parts of the rectum during 15 years, while another had six in 14 years. One patient had seven adenomata in 6 years and another nine in 8 years. One patient after having two recurrences went 6 years and then developed another.



Fifty cases of adenomata in the rectum and sigmoid.

As will be seen, by a study of the accompanying chart, the proportion of cases in which other adenomata developed was very high; actually this occurred in about 50 per cent. It is too easily assumed that because an adenoma has been removed months or years before from the rectal mucosa, that the finding of another subsequent adenoma is due to a recurrence of the original tumour. I am convinced that such is not the case, but that the subsequent adenomata are almost always new primary tumours, not parts of the first tumour. In this series of cases careful note was taken of the situation of the secondary adenomata, and it was almost invariably found that the secondary tumours were not in the same position as the original tumours that had been removed. In very many cases the secondary tumours were inches away from the original site, or on a different aspect of the rectum altogether. In some cases the secondary tumours were much higher up in the colon. A reference to the chart shows that in a large number of cases adenomata were removed which were proved to be innocent in character, but that subsequently, sometimes many years later, another tumour formed which was definitely malignant. This actually took place in 12 out of a total of 50 cases.

While I was well aware of the fact that adenomata were liable, if left alone, to change into malignant growths, it has been a surprise to find that there were such a large number of cases where patients have developed malignant adenomata subsequent to the removal of an innocent one. I think we are justified in saying that adenomata of the bowel epithelium are not innocent in any sense, and are merely a stage in the development of cancer.

An adenoma may grow to a very large size without becoming malignant. Some of those in this series covered an area of four or five inches, and some were as large as oranges, but were not malignant in any part. In a few instances, owing to the age of the patient, or other infirmities, very large adenomata have not been removed, but have been observed for a number of years and have not shown any signs of malignant change, while on the other hand comparatively small ones have been observed to become malignant tumours in a few months. Generally speaking, however, it has been my experience that small adenomata are very seldom found to be malignant, a certain optimum size seems to be necessary before a malignant change occurs.

It seems that once a patient has developed an adenoma in the rectum the mere removal of the tumour, however thoroughly it is done, is not sufficient to prevent that patient from developing another adenoma, or even from developing cancer.

When the entire rectum has been removed for an adenoma there has been no instance of the formation of a second primary tumour in this series of cases. The only cases where a complete excision has been performed are those cases where on account of the size or extent of the adenoma, the only feasible method of removal was by complete excision. The inference appears to be that complete excision of the rectum is the only effective way to rid the patient of adenomata, but although this may be the best method on purely theoretical grounds it is for many reasons seldom possible. This series, however, shows that if the patient is carefully examined regularly every four or five months secondary tumours can be detected in the very early stage when they can be removed with the cautery, or by burning them with fuming nitric acid, and that by such means patients can be protected from any serious development for very many years. In only one of these 50 cases in which this method was adopted, did the patient develop a malignant tumour, and in that one case the innocent tumour was in the rectum and the secondary one, which became malignant, occurred in the pelvic colon out of reach of the sigmoidoscope.

REMARKS

These cases seem to prove that an adenoma of the rectum, or colon, is not an innocent tumour in any
sense and that in fact adenomata are merely a st
in the development of malignant tumours, a
should be so treated. At a certain age certain c
of the bowel epithelium exhibit a tendency to unde
hyperplasia ; in other words, they start to gr
at a speed which is much in excess of the nor
requirements of the tissue wastage and a tum
results. This tendency is not, however, confined
one cell or group of cells, but appears to be fai
widespread. With the result that the removal of
adenoma does not prevent the development of othe

I believe that what happens, when a tum
forms, is that a change or gene mutation occurs
start with in the nucleus of a single cell resulti
in an excessive rate of reproduction of that cell
compared with the reproduction of normal cells
the same tissue. The adenoma result from
excessive reproduction of this single cell. T
tumour is composed of normal cells differing, as
as we can observe, from other cells only in the f
that its cells are reproducing themselves too fa
This tendency for a mutation or change of th
character to take place, is often however, pres
in a number of different cells in a fairly wide ar
The exciting cause of the change may be due
genetic instability, or to some factor in the envir
ment, and the fact that it has occurred in one
does not prevent the same change from taking pl
later on in other cells.

It is becoming increasingly evident that more
be learnt about the problem of tumours by a care
study of adenomata of gland tissue than by a stu
of actually malignant tumours themselves. T
tumour problem must be the same, or very similar
all true tumours. Indeed it is possible that essent
difference between simple and malignant tumours
dependent upon their different rates of grow
In a paper just published, J. C. Mottram [5] describ
the results of a study of the rate of growth of
warts in mice and postulates the possibility that
growth rate decides the question of innocency
malignancy. Where the growth rate is slow
tissues are able to set up a protective reaction agai
the process, but when the growth rate is fast t
protective reaction breaks down and invasion
other tissues by the rapidly reproducing cells ta
place.

From a practical point of view local removal of
tumour would appear to be sufficient *if* the patie
is carefully watched at four-monthly intervals duri
the next five to ten years, so that fresh tumours can
removed at once before they have had an opportuni
of becoming malignant. But unless the patient
kept under observation in this way the developme
of other tumours is very likely to occur unobserve
The frequency of such a happening appears to
about 50 per cent., and a considerable danger exis
of malignancy supervening.

Only one case that was kept under observation
this series has developed a malignant growth, and
that instance it was in the colon too high up to
seen. It may, I think, be justly claimed that wi
this exception, a large number of the patients
this series of cases have been prevented by surgic
treatment from developing cancer.

exhibit no evidence of malignant change in any t of its structure, that nothing further is to be ed, and that the patient is cured in the true sense. ; no real evidence has hitherto been available on ch to base such an assumption, and as I shall to show, it is as a matter of fact quite unjustified false. The patient is by no means certainly cured the removal of the adenoma, however completely removal is carried out. It is probably true that particular adenoma which has been removed will return, but the changes in the epithelial cells which e resulted in the formation of the adenomatous nour may still be present and other adenomatous nours are liable to form in the neighbouring thelium.

THE INQUIRY

decided to attempt to trace the after-history of a e number of cases of simple, so-called innocent, nomata of the rectum and colon, and to see what portion of recurrences there were, and in what ations they occurred after, what is generally sidered, adequate surgical procedures. Fortunately many years I have made it a habit to examine all es where a simple adenoma has been removed n the bowel at periodic intervals, both in hospital private practice. It has thus been possible to dy the after-history of 50 cases.

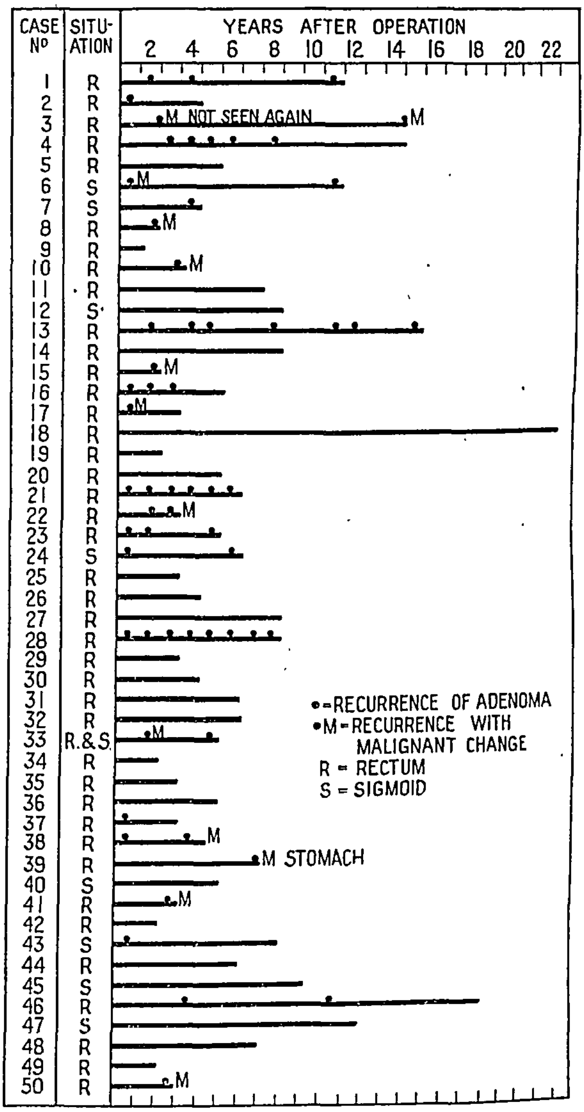
For the purpose of this investigation I considered viser to leave out entirely all cases of that curious ease adenomatosis, or multiple adenomata, where re are numerous tumours more or less throughout whole colon, as adenomatosis has already been y thoroughly studied and appears to be a disease irely of genetic origin, and although in the present te of our knowledge it is not possible to draw any y hard-and-fast distinction between cases of gle adenomata and cases of adenomatosis, I feel t to mix all the cases together would not be helpful. erefore, all cases of adenomatosis have been entirely luded. Only those cases have been taken in which original adenoma was adequately removed accord- to our modern standards by some surgical cedure, and where it has been possible to trace the penings for at least a year afterwards.

The method of removing the adenomata has varied siderably. In those cases where the tumour has sented itself as a pedunculated polyp it has been noved by a wire diathermy snare, or by ligating pedicle when this was possible. When the tumour been large and sessile, it has been cut out with f an inch or more margin of healthy mucous mbrane, either through the rectum or from behind er removing the coccyx and the wound in the rectum ored by stitching. In a few cases a local resection s performed and in some cases where the tumour s very large the rectum has been entirely excised the usual methods. In all cases the original adenoma been properly examined histologically after noval, generally by a series of sections, and its racter as an innocent adenoma verified.

Most of the cases have been examined sigmoido- pically at regular intervals, many of them every r months, for a number of years after the original ration, and the findings have been most carefully cked both clinically and pathologically. Some ients have, of course, refused to return for periodic mination, or have been unable to do so, but in a nber of cases which have not returned the subse- nt history has been obtained from the patient's dical adviser.

Out of the total of 50 cases there were 25 in which other tumour developed, and 12 where malignant nours, adenocarcinoma, subsequently developed. In 25 cases there was no recurrence of any kind. In 13 cases other adenomata developed more than once in different sites. The average age of the patients was about 60. One of the cases counted among the recurrences is a patient who developed a cancer of the stomach seven years after removal of the original adenoma.

Some of the cases were very remarkable. Thus, one patient had no less than eight adenomata in different parts of the rectum during 15 years, while another had six in 14 years. One patient had seven adenomata in 6 years and another nine in 8 years. One patient after having two recurrences went 6 years and then developed another.



Fifty cases of adenomata in the rectum and sigmoid.

As will be seen, by a study of the accompanying chart, the proportion of cases in which other adenomata developed was very high; actually this occurred in about 50 per cent. It is too easily assumed that because an adenoma has been removed months or years before from the rectal mucosa, that the finding of another subsequent adenoma is due to a recurrence of the original tumour. I am convinced that such is not the case, but that the subsequent adenomata are almost always new primary tumours, not parts of the first tumour. In this series of cases careful note was taken of the situation of the secondary adenomata, and it was almost invariably found that the secondary tumours were not in the same position as the original tumours that had been removed. In very many cases the secondary tumours were inches away from the original site, or on a different aspect of the rectum altogether. In some cases the secondary tumours were much higher up in the colon. A reference to the chart shows that in a large number of cases adenomata were removed which were proved to be innocent in character, but that subsequently, sometimes many years later, another tumour formed which was definitely malignant. This actually took place in 12 out of a total of 50 cases.

While I was well aware of the fact that adenomata were liable, if left alone, to change into malignant growths, it has been a surprise to find that there were such a large number of cases where patients have developed malignant adenomata subsequent to the removal of an innocent one. I think we are justified in saying that adenomata of the bowel epithelium are not innocent in any sense, and are merely a stage in the development of cancer.

An adenoma may grow to a very large size without becoming malignant. Some of those in this series covered an area of four or five inches, and some were as large as oranges, but were not malignant in any part. In a few instances, owing to the age of the patient, or other infirmities, very large adenomata have not been removed, but have been observed for a number of years and have not shown any signs of malignant change, while on the other hand comparatively small ones have been observed to become malignant tumours in a few months. Generally speaking, however, it has been my experience that small adenomata are very seldom found to be malignant, a certain optimum size seems to be necessary before a malignant change occurs.

It seems that once a patient has developed an adenoma in the rectum the mere removal of the tumour, however thoroughly it is done, is not sufficient to prevent that patient from developing another adenoma, or even from developing cancer.

When the entire rectum has been removed for an adenoma there has been no instance of the formation of a second primary tumour in this series of cases. The only cases where a complete excision has been performed are those cases where on account of the size or extent of the adenoma, the only feasible method of removal was by complete excision. The inference appears to be that complete excision of the rectum is the only effective way to rid the patient of adenomata, but although this may be the best method on purely theoretical grounds it is for many reasons seldom possible. This series, however, shows that if the patient is carefully examined regularly every four or five months secondary tumours can be detected in the very early stage when they can be removed with the cautery, or by burning them with fuming nitric acid, and that by such means patients can be protected from any serious development for very many years. In only one of these 50 cases in which this method was adopted, did the patient develop a malignant tumour, and in that one case the innocent tumour was in the rectum and the secondary one, which became malignant, occurred in the pelvic colon out of reach of the sigmoidoscope.

REMARKS

These cases seem to prove that an adenoma of the rectum, or colon, is not an innocent tumour in any sense and that in fact adenomata are merely a stage in the development of malignant tumours, and should be so treated. At a certain age certain cells of the bowel epithelium exhibit a tendency to undergo hyperplasia; in other words, they start to grow at a speed which is much in excess of the normal requirements of the tissue wastage and a tumour results. This tendency is not, however, confined to one cell or group of cells, but appears to be fairly widespread. With the result that the removal of one adenoma does not prevent the development of others.

I believe that what happens, when a tumour forms, is that a change or gene mutation occurs to start with in the nucleus of a single cell resulting in an excessive rate of reproduction of that cell as compared with the reproduction of normal cells of the same tissue. The adenoma result from the excessive reproduction of this single cell. The tumour is composed of normal cells differing, as far as we can observe, from other cells only in the fact that its cells are reproducing themselves too fast. This tendency for a mutation or change of their character to take place, is often however, present in a number of different cells in a fairly wide area. The exciting cause of the change may be due to genetic instability, or to some factor in the environment, and the fact that it has occurred in one cell does not prevent the same change from taking place later on in other cells.

It is becoming increasingly evident that more can be learnt about the problem of tumours by a careful study of adenomata of gland tissue than by a study of actually malignant tumours themselves. The tumour problem must be the same, or very similar for all true tumours. Indeed it is possible that essential difference between simple and malignant tumours is dependent upon their different rates of growth. In a paper just published, J. C. Mottram[5] describes the results of a study of the rate of growth of tar warts in mice and postulates the possibility that the growth rate decides the question of innocency or malignancy. Where the growth rate is slow the tissues are able to set up a protective reaction against the process, but when the growth rate is fast this protective reaction breaks down and invasion of other tissues by the rapidly reproducing cells take place.

From a practical point of view local removal of the tumour would appear to be sufficient *if* the patient is carefully watched at four-monthly intervals during the next five to ten years, so that fresh tumours can be removed at once before they have had an opportunity of becoming malignant. But unless the patient is kept under observation in this way the development of other tumours is very likely to occur unobserved. The frequency of such a happening appears to be about 50 per cent., and a considerable danger exists of malignancy supervening.

Only one case that was kept under observation in this series has developed a malignant growth, and in that instance it was in the colon too high up to be seen. It may, I think, be justly claimed that with this exception, a large number of the patients in this series of cases have been prevented by surgical treatment from developing cancer.

ON MEASURING RED BLOOD-CELLS

WITH SPECIAL REFERENCE TO A NEW DIFFRACTION APPARATUS

BY ADRIANUS PIJPER, M.D. Leiden
PATHOLOGIST TO THE PRETORIA HOSPITAL

(WITH ILLUSTRATIONS ON PLATE)

THE accompanying figures are reproduced from photographs of coloured semicircles as they appear on the ground-glass screen of the new diffraction apparatus for measuring red cells to be described here. On the left in both pictures are the diffraction semicircles produced by "normal" blood; on the right in Fig. I. are semicircles from a case of pernicious anæmia, and those in Fig. II. are from a case of subacute combined degeneration of the spinal cord. The differences between these three types of diffraction patterns are obvious enough, even in these black-and-white photographs. They are very striking when seen in their full colours in the apparatus. The patterns produced by secondary anæmias and by microcytic anæmias are quite different again from those reproduced here.

ROUTINE AND RESEARCH

A "routine" blood examination usually consists of hæmoglobin estimation, red cell count, and microscopic inspection of a stained smear. Additional investigations on the red cells, including red cell measurements, are usually regarded as "research."

Price-Jones' work[1] established the value of red cell measurements. But for its laboriousness such a microscopic method would have become "routine." But nobody can afford to spend a couple of hours measuring red cells every time a blood smear is made. Thus the paradoxical situation has arisen that measuring is mostly done when it is least needed. It is used to confirm, not to inquire. It has been said that a diagnosis of pernicious anæmia often comes as a surprise.[2] The truth of this is brought home to one when red cell measurements are a routine measure. Without red cell measurements the differential diagnosis of anæmias outside highly specialised clinics depends chiefly on calculation of the hæmoglobin-index and inspection of a stained smear, of which the former is subject to a 20 per cent. error at least, while the interpretation of the latter is largely a matter of opinion. Feeble as this method is elsewhere, the calculation of the "index" breaks down completely in countries like the Transvaal, where many people live in perpetual sunshine at an altitude of five or six thousand feet, with frequent and sudden descents to, and returns from, sea-level, in the shape of rapid trips to the coast or down a mine. Counts of 6 million red cells in anæmic persons are not at all unusual here.

The very laboriousness of measuring red cells microscopically and plotting the results seems to impress many people as being a guarantee of accurate results. That method of fixing and staining, source of light, properties of substage condenser, quality and especially aperture of objective, fineness of pencil point or thickness of graduations of micrometer, boredom and personal equation of the observer all affect the results is too often forgotten. In fact, a Price-Jones curve consists of two curves superimposed. One is the curve of actual diameters, the other is the "normal curve of error." These remarks do not attack the usefulness of the method, they are merely meant to counteract the growing but unwarranted tradition that a Price-Jones curve is the last word in accurate and reliable research. Critical microscopists know better, and the hardly measurable does not become more measurable by spending more time over it.

THE DIFFRACTION METHOD

The diffraction method of measuring red cells, which I first described in 1919,[3] and applied diagnostically in 1924,[4] was greatly improved by me in 1929.[5] The criticisms which are levelled against the method are all concerned with the admittedly somewhat primitive technique of 1924. This is largely due to the fact that after 1924 from various sources several apparatuses were put on the market, embodying this simple technique, sometimes even without an understanding of its leading principles. The improved method of 1929, requiring more insight and more elaborate apparatus, did not lend itself to this popularisation. Except for the work of Ponder[6] and Miller[7] nothing new was added to the method by all these efforts at popularisation and simplification. They may be regarded, however, as an indication that the need for a quick and reliable method of measuring red cells is universally felt.

IMPROVED DIFFRACTION METHOD

The full advantages of the improved diffraction method, as used by me, and a few others, with complete satisfaction, are now available in a new and self-contained apparatus. It is built on the lines laid down by me in 1929, but owes its compactness to the ingenuity of Prof. Siedentopf, of the firm of Zeiss, who interested himself in the method, and after thorough investigation designed a suitable apparatus.* This has the advantage that the source of light is built-in, and once it has been put up, which is a simple matter, no further adjustments are required. There is a horizontal stage, on which two blood smears can be placed. Their diffraction patterns, produced by about a million cells, appear on a ground-glass screen which forms the top of the apparatus. A partition placed in the middle of the apparatus cuts out half of each diffraction pattern, and the remaining semicircles appear in close apposition on the screen, facilitating comparison, as illustrated in Figs. I. and II.

READING RESULTS

Each diffraction pattern consists of a bright white centre, surrounded by an orange ring, and then follow the colours of the spectrum in natural order, starting with violet and finishing up with red. After that green and red circles alternate with one another. For practical purposes the cardinal points are the positions of the inner edge of the violet circle (V), of the outer edge of the red circle (R), and the position of the yellow circle (Y).

Normal blood smears show little variation in the positions of these three rings. The limits of what might be called normal variation are given in the Table. The meaning of this individual variation has been discussed elsewhere.[8] For routine work one compares the diffraction rings produced by a blood smear from a healthy person giving average readings with those produced by the patient's blood smear. This will give information as to the mean diameter of the patient's red cells, and also as to the degree of anisocytosis and sometimes of poikilocytosis present in his blood.

---

* The apparatus is sold by Messrs. Carl Zeiss, Jena, as "Blutzellenprüfer nach Dr. Pijper" or "Dr. Pijper's Bloodcelltester." A special booklet issued with the apparatus gives full details and working directions.

The principles on which this is done have been outlined before.[4 5] The reliability of this information has been amply confirmed by me in actual clinical practice during the past seven years, and also by control microscopic measurements undertaken for this purpose.[9] For the proper use of the diffraction method it is essential to adhere to these principles and to abide by the rules laid down in connexion with this apparatus for reading results. No satisfactory results can be obtained by merely estimating the size of a "halo" or by measuring the diameter of a single coloured ring, chosen at random. The range of variation of the three coloured rings mentioned above (V, Y, and R) in different anæmias is given in the Table. *It is not necessary to make actual measurements in every case.* After some practice the direct comparison with normal blood enables one to get the required information simply by glancing at the diffraction patterns. Thus one pattern will give a diagnosis of microcytic anæmia, another will be characteristic of pernicious anæmia, while a third will exclude pernicious anæmia and make a decisive diagnosis of secondary anæmia. Again, there is a difference between the typical pattern of pernicious anæmia with pronounced anæmia and those forms where nervous symptoms predominate and changes in the blood are hardly detected except by red cell measurements. Measurements of the circles are performed directly by means of a pair of compasses on the ground glass along the black dividing line between the two patterns, or indirectly by placing a piece of transparent paper on the ground glass and marking the circles on the paper, with subsequent measurement. This last method has the additional advantage of giving permanent records which can be attached to the hæmatological report.

Rings in mm.	Pernicious anæmia.	Normal.	Secondary anæmias.	Microcytic anæmias.	Hæmolytic icterus.
V	22–29	33–35	28–32	35–38	39–43
Y	50 and less	52–56	55–56	57–61	63 and more
R	58–64	65–70	67–77	74–78	90 and more

It is convenient to divide pathological diffraction patterns into three types, depending on the facts that the diameter of the yellow circle (Y) varies in inverse ratio to the mean diameter of all the cells, and that the distance between V and R increases as anisocytosis increases. Poikilocytosis, if pronounced, interferes with the regularity of the patterns and produces watery colours.

TYPE 1.—All three rings small; for measurements see the Table. Distance between V and R *relatively* large. This pattern means macrocytosis and pronounced anisocytosis. This is typical of pernicious anæmia. In the anæmic form there is often so much poikilocytosis that the colours are watery (Fig. I.). In the nervous form there often is little poikilocytosis and the colours are bright (Fig. II.).

TYPE 2.—Yellow ring of normal diameter, which means normal mean diameter of cells; for range of variations see the Table. Ring V is smaller than normal, ring R is larger than normal. This means that there is more anisocytosis than normal; its degree can be read off from the distance between V and R, as compared with the normal pattern on the left. The colours may be somewhat diffuse, on account of their being spread out over a larger area, but they only become watery when there is distinct poikilocytosis as well. This is the pattern I find in secondary anæmias, whatever their causation (infections, hæmorrhages, other diseases).

TYPE 3.—Counterpart of Type 1. All three rings larger than normal, and distance between V and R often relatively increased, as a result of anisocytosis; for range of variations see the Table. This is the pattern I find in microcytic anæmias, and also in hæmolytic icterus. Untreated cases of the latter disease during periods of exacerbation may show truly enormous rings. Extirpation of the spleen, or quiescent periods, may reduce them to more normal size.

In all three types comparison of the diffraction patterns produced by blood smears taken at intervals affords probably the most sensitive and quickest method of following the progress of the case.[10]

CALCULATION OF RED CELL DIAMETERS

The mean diameter of the red cells in all cases is calculated by taking the diameter of the yellow circle (Y) in millimetres, subtracting one millimetre *(for the image of the source of light), and dividing* into 395. The result is the mean diameter in microns. Example: the yellow circle measures 54 mm.; dividing 395 by 53 gives 7·5 microns.

It is possible, by means of a special formula,[5] to express the degree and quality of anisocytosis in diameters of red cells. In practice this is hardly felt *to be necessary. At most, one calculates the mean* cell diameter and reads the anisocytosis from the relative position of the three rings.

DISCUSSION

It is not always possible to say that a given diffraction pattern is definitely pathological. There *are transitions between the range of normal variation* as given in the Table, and definitely pathological states. Thus a yellow circle of 52 mm. (red cell diameter= 7·7 microns) is still normal, and one below 50 (red cell diameter=8·1 microns) is definitely pathological, but values between these two figures may have various meanings. There exist macrocytoses of varying degrees of different origins, which are not very well established at the present time, and will probably become better known through more universal use of red cell measurements.

It is not claimed that the improved diffraction method is a short cut to hæmatological diagnosis. It is not suggested that the usual routine measures should be abandoned, but red cell measurements have proved their worth in research, and thus have become essential for routine examinations. They give information which no other method can give. That they have not come into their own is due to the fact that pathologists thus far have not had a satisfactory method of ascertaining them. It would be easy to extract a series of cases from my own laboratory records alone where the diffraction method supplied a diagnosis when other measures had failed, more especially in the nervous form of pernicious anæmia, but also in acholuric jaundice. Apart from those instances in which valuable positive information is gained, there are other instances where application of the diffraction apparatus in this form permits the immediate exclusion of a suspected diagnosis. A diffraction pattern of Type 2 or 3, for instance, never occurs in pernicious anæmia. Patients with a diffraction pattern of Type 2 should receive the benefit of a further investigation so as to lay bare the cause of their secondary anæmia.

It takes very little time or trouble to become conversant with the workings of the apparatus, and afterwards only a few seconds to secure information as to diameters of red cells in every blood smear dealt with. The importance of this information can only be appreciated by actually using the method, which, however, is not meant to be used to the exclusion of other methods. For this reason the apparatus is not intended so much for the busy practitioner as for the clinical laboratory, where the workers who, so far, have not had a method that was satisfactory for practical purposes can fit its results into other findings.

Clinical and Laboratory Notes

BILATERAL BRONCHIAL OBSTRUCTION

BY A. S. HALL, M.B. Camb., M.R.C.P. Lond.

PHYSICIAN TO THE ROYAL CHEST HOSPITAL, LONDON; DIAGNOSTIC PHYSICIAN TO THE INSTITUTE OF MEDICAL PSYCHOLOGY

(WITH ILLUSTRATIONS ON PLATE)

BRONCHIAL obstruction, other than by carcinoma, is beginning to occupy the attention of physicians rather more than formerly, and certain syndromes are becoming better known. It has long been recognised, for example, that complete obstruction produces collapse of the lung peripheral to the block, but hitherto it has not been generally understood that obstruction which is not quite complete is sometimes associated with a sort of valve action, with emphysema of the lung supplied by the bronchus. The following case illustrates both these sequels to blockage.

The patient was a boy aged 5, who, a year before admission had had a pneumonic condition of the left lower lobe and several subsequent mild attacks of bronchitis. He was admitted to the Royal Chest Hospital on the third day of an illness in which the chief symptoms were extreme dyspnœa and pain in the abdomen. Clinically this was a case of right lower lobe pneumonia, although no bronchial breathing was heard, and radiography seemed to confirm this diagnosis. (Fig. I. on Plate.) Progress was not satisfactory, however, and a later radiogram (Fig. II.) showed some collapse of the right middle and lower lobes. A foreign body was suspected and on the twenty-sixth day of his illness he was bronchoscoped by Mr. A. M. Zamora, who removed a piece of peanut. The left bronchus was not inspected. X ray examination several days later showed almost complete re-expansion. (Fig. III.)

He still continued coughing, showing signs of bronchitis, and some weeks later a Mantoux test (0·0001, OTB) was done, this being followed in 36 hours by a marked local reaction, extreme dyspnœa, and high fever. Examination showed hyper-resonance of the left lung except at the base and complete absence of breath sounds. A diagnosis of left bronchial obstruction was made and it was thought to be due to swelling of the mediastinal glands as part of the tuberculin reaction. Radiography showed no enlargement of the glands, but it showed collapse of the left lower lobe. (Fig. IV.) The child gradually recovered, although the breath sounds in the left chest remained weak and he was discharged from hospital; two days later he was readmitted in exactly the same condition as that following the Mantoux test. He was again bronchoscoped by Mr. Zamora, who this time removed a pedicled granuloma from the left main bronchus. Recovery was rapid and the child has been well ever since. A lipiodol radiogram shows a normal bronchial tree. (Fig. V.)

The sequence of events is interesting: (1) a pneumonic condition of the left lower lobe a year before admission, possibly due to obstruction by a granuloma; (2) the inhalation of a peanut, producing complete obstruction of the right lower bronchus with collapse of the right middle and lower lobes; (3) removal of the peanut; (4) complete obstruction by a granuloma of the left lower lobe bronchus, with collapse of the lobe and incomplete obstruction of the left upper lobe bronchus with emphysema of the upper lobe; (5) removal of the granuloma; (6) bronchial tree normal on lipiodol examination.

STREPTOCOCCAL SEPTICÆMIA TREATED WITH ANTITOXIN

BY R. M. BATES, F.R.C.S. Eng., D.P.M.

RESIDENT MEDICAL OFFICER, STOKE PARK COLONY, NEAR BRISTOL

A Mongol boy aged 13 was admitted to the hospital at Stoke Park Colony suffering from a typical attack of acute gastro-enteritis.

Two days later, following a rigor, the temperature rose to 105° F. and a small area of cellulitis was noticed upon the front of the left leg. The stools, which like the vomited material had been grass-green at the onset of the attack, were now normal in colour but still relaxed. Bacteriological examination of urine and fæces gave a negative result, but the urine contained a trace of albumin. The patch of cellulitis rapidly increased in size and was followed by a similar one on the dorsum of the left foot. Pus formation was slow, and meanwhile new areas of cellulitis appeared on the dorsum of the right foot, at the left elbow, and on the inner side of the right knee. Six days after admission to hospital the patient showed signs of a left lower lobar pneumonia. At the end of the second week diminished breath sounds at the same situation suggested the presence of fluid, and aspiration produced 7 c.cm. of blood-stained purulent fluid. On the same day the superficial abscess on the dorsum of the left foot was incised. Direct films and cultures from the pus in each case showed streptococci. An intramuscular injection of concentrated streptococcal antitoxin (scarlatina) 4 c.cm. was given the same day and continued in the same dosage twice daily.

During the third week the pleural cavity was emptied three times by syringe. On the first occasion 40 c.cm. of pus were withdrawn, 30 c.cm. on the second, and 6 c.cm on the third and last occasion, one week after the original needling. The pus obtained at each aspiration gave a pure culture of *streptococci*. Thereafter the lung expanded well, breath sounds returned, and there were no furthe signs of fluid. The areas of cellulitis formed abscesses and these were incised and drained as pus formed. Again the pus in each case gave pure cultures of streptococci.

During the fourth week, after the temperature and pulse-rate had settled, the antitoxin was reduc
4 c.cm. once daily. It was suspended altogeth
the fifth week, but recommenced during the
to the formation of a deep-seated abscess
arm. This was drained and 4 c.cm. were giv
for a further six days. In all, five abscesses
and two areas of cellulitis resolved without a
tion. The patient was discharged from h
weeks after admission.

In this case the streptococcal infection
originated in the alimentary tract; the
and empyema arose during the course o
cæmia. One week's treatment by aspiratic
toxin sufficed to clear up the empyema.

incision was seven and a half days. Two of these latter were deep-seated.

Concentrated antistreptococcal serum may be given to children over a long period and in large amount. This patient received 136 c.cm. without any evidence of serum sickness. Urticaria appeared during the third week when the dosage was 8 c.cm. daily, but disappeared spontaneously in 24 hours.

I am indebted to Mrs. Burden, warden of Stoke Park Colony, for her kindness in paying the expenses of this treatment, and to Prof. R. J. A. Berry, director of medical services, for permission to publish the case.

POLYRADICULONEURITIS WITH ALBUMINO-CYTOLOGIC DISSOCIATION OF THE CEREBRO-SPINAL FLUID

BY S. ANTOŠ, M.D.
ASSISTANT PHYSICIAN, MEDICAL CLINIC, MASARYK UNIVERSITY, BRNO, CZECHOSLOVAKIA

THE condition described by French neurologists as polyradiculoneuritis appears in the initial stages to be a very grave illness, but has a benign course and carries a reasonably good prognosis.

A man aged 55, never previously ill, got soaked through on his way to work on May 29th; he had to travel by train for several hours, shivered and became feverish. The next day he felt unwell. On the third day he woke up with pains in his back and neck, arms and legs, and with paræsthesiæ in the limbs. It was a great effort to walk, and weakness increased daily. His temperature, however, was normal from the third day onwards. He was admitted to hospital on the seventh day, with slight rigidity of the neck and great tenderness to pressure over the brachial plexuses on both sides, and on the nerve trunks of the extremities. Lasègue's sign was present on both sides. The pulse-rate was 84, regular, and the temperature 36·4° C. The pupils reacted well and nothing abnormal was found in the ears, sinuses or elsewhere, except for a slight reddening of the throat.

During the next ten days the complete nervous syndrome of bilateral facial palsy and quadrilateral paralysis appeared. Muscular hypotony was accompanied by loss of tendon reflexes, and a quantitative diminution of sensibility to electric currents. The paresed peroneal muscles showed a partial reaction to degeneration. His muscular weakness compelled him to stay in bed, where he had to be fed by a nurse, as the only movements he could carry out were feeble ones of the shoulders and thighs. The sphincters were not affected. He remained in this condition for five weeks, and then the pareses disappeared gradually in the order in which they had developed; the facial palsy first, then that of the arms, and finally that of the legs. Ten months after admission he was discharged almost recovered, having only a very slight weakness of the peronei on both sides and absence of both knee-jerks.

An important diagnostic point was the marked excess of albumin without high cell count in the cerebro-spinal fluid. Lumbar puncture was performed three times; five cells were found. Pandy's, Nonne-Apelt's, and Weichbrodt's reactions were all strongly positive. The gold reaction was at first, 0112331000; later, 0135552100; and finally, 00011000; and the benzoin reaction was 2202 the first time, but negative the second and third times. The Wassermann reaction was negative in both blood and cerebro-spinal fluid, and cultures from both were sterile. He was treated by artificial pyrexia (typhoid vaccine, &c.) and by galvanotherapy and massage.

Guillain-Barré[1] described this syndrome for the first time in 1916. They said that the course was benign, but Margulis[2] and others showed that it might be subacute. The condition seems to be due to an unknown virus, probably filtrable. It has been described as secondary to osteomyelitis, epidemic parotitis, and other diseases, but recently these nervous complications have been ascribed to a neurotropic virus rather than to the primary disease. Popek,[3] however, does not agree. In our case the long exposure to cold and damp seems to have had some ætiological significance. We were able to give a favourable prognosis, though the patient was still very ill, as soon as we had correctly diagnosed his condition. The differential diagnosis is therefore of considerable practical importance.

MEDICAL SOCIETIES

MEDICAL SOCIETY OF LONDON

ANNUAL ORATION

Sir WILLIAM WILLCOX delivered the annual oration *of this society on May 13th, and took as his subject*

Toxic Drugs: their Use and Misuse

During the present century, he said, the linkage between chemical constitution and pharmacological [illegible]on has been so closely studied that the pharmaco-[illegible]an to some extent deduce the therapeutic [illegible] organic compound. He can also foretell [illegible]ations in action follow modification in [illegible] thus in research on barbituric acid [illegible]s the substitution of an ethyl group by an [illegible]yl, or other radical leads to definite variation [illegible]cological action. The result of such changes [illegible]that enormous numbers of drugs of organic [illegible] been introduced, and sometimes their [illegible] has been too hasty. The borderland between [illegible]acological effect and a toxic or poisonous [illegible] often narrow, and one should be chary [illegible]ing drugs unless one has personal knowledge [illegible]afety in use. A glowing advertisement [illegible]lieve one of responsibility.

In 1934 an expert Committee (Poisons Board) was appointed with an advisory capacity in regard to the additions to the Poisons List and regulation of supply of substances having a toxic as well as a therapeutic action. In the report of this Board, which is to be issued, regulations will appear which will limit the supply of certain drugs of powerful therapeutic action to medical prescription. The public will be unable to purchase these drugs on their own initiative and their use will therefore be under medical supervision and control.

TOLERANCE AND INTOLERANCE

One of the most important functions of the liver is to protect the body against exogenous poisons such as drugs, and also against the complex substances formed during digestion and metabolism. When absorbed by the alimentary tract such poisons are conveyed by the portal vein to the liver which acts as the first line of defence; when they are introduced into the general circulation (e.g., by injection), the liver absorbs much of them from the blood stream and so protects the other tissues of the body. The liver in this way bears the brunt of the attack and in so doing its cells may undergo damage (cloudy swelling, fatty degeneration, or even necrosis). It is known that the presence of glycogen in the liver cell increases its resisting power to poisons, and it is therefore advisable that glucose should be taken freely within a few hours of the administration of a toxic drug, such as a general anæsthetic or arsenobenzol derivative. In cases where the liver has undergone necrosis and life persists some days after the taking of the poison the cause of death will be autointoxication from hypofunction of the liver (hypohepatism) and little or no poison may be found in the body.

If a person is allergic a toxic drug in normal dose may have an enhanced and even dangerous effect. A history or evidence of defect in liver or kidney function, the presence of some intercurrent infection or of some toxic focus of infection, a highly sensitised nervous system—all these suggest the likelihood of allergy. Hence these are all points which require careful consideration before the administration of toxic drugs. Certain persons, moreover, show a special sensibility or idiosyncrasy to a particular drug (quinine, belladonna, morphine, iodides, or arsenobenzol compounds), so that toxic symptoms arise from even small doses. The continued administration of certain drugs (morphine, heroin, cocaine) may, on the other hand, produce a tolerance to very large doses; but such tolerance may suddenly be lost, owing to intercurrent infection for example, so that the customary large dose becomes a dangerous one. In the case of many toxic drugs such as the barbiturates, or the quinoline group (cincophen), tolerance is never established and an overdose is always a dangerous dose.

SOME TOXIC DRUGS

Morphine and Heroin are invaluable, and timorous prescribing is more likely to lead to addiction than the employment of adequate amounts. Morphine may be generously given for organic disease and the comfort of the patient ensured provided that measures are taken for dealing with the cause of the symptoms. The use of morphine and heroin for psychical symptoms, however, is attended with danger of addiction. Furthermore these drugs are poisons to the liver and kidney, and if there is any evidence of defective function of these organs such as jaundice, or suppression of urine, even small doses are dangerous. In these circumstances minute doses, such as gr. 1/20 8-hourly, may give a full therapeutic effect.

Eukodal, Dicodid, and Dilaudid are recently introduced substitutes for morphine and heroin. The claim that they are free from risk of drug addiction has not been established, since several examples of addiction from their use have come to the speaker's notice.

Arsenobenzol compounds of the salvarsan and neosalvarsan type are perhaps the most valuable of modern therapeutic discoveries, but care is essential if toxic accidents are to be avoided. Thus impairment of function of the liver and kidney, and the presence of acute cerebral lesions of syphilitic type would be contra-indications for use. It must be remembered that an intravenous dose is not fully excreted until a fortnight has elapsed, so that the giving of full doses weekly is likely to give rise to toxic symptoms after a few doses. Accordingly when weekly doses are given they should be submaximal. Glucose premedication is a wise procedure. There are patients, moreover, who have an idiosyncrasy to aresenobenzol compounds.

Antimony.—Organic preparations of antimony and the potassium and sodium tartrates of this element have been used with success for tropical diseases such as kala-azar, bilharzia infections, and trypanosomiasis. The same precautions as for arsenobenzol compounds are indicated. A countess's fatal administration of Dr. James's fever powders (consisting of a full dose of potassium antimony tartrate) to her butler last century led to the comment that "there are more elements for success in the treatment of illness than a well-stocked medicine chest."

Bismuth preparations given intramuscularly and subcutaneously have valuable uses in the treatment of syphilis. There is a risk of severe exfoliative dermatitis in some allergic cases and the slightest sign of any skin reaction is an indication for complete discontinuance.

Gold.—Organic compounds of gold have a limited but useful place in the treatment of tuberculosis of lung, skin, and other organs. They have been recently introduced for the treatment of rheumatoid arthritis, but the risk of severe exfoliative dermatitis, occurring in not a few cases, is a warning for the utmost care in their employment. Other safer methods of treatment for chronic arthritis are preferable and more efficient. A few cases of toxic jaundice have been reported after the use of gold preparations.

Mercury.—Mercurochrome, an organic compound of mercury, has been used for septicæmic infections, but its use is not free from risk and has fallen into abeyance. Novasurol and Salyrgan are organic compounds of mercury having a powerful diuretic action when given intravenously. The toxic effect of mercury on the kidney calls for meticulous care.

Quinoline derivatives such as cinchophen (also known as Atophan, Agotan, Phenoquin, Atophanyl, Atoquinol) have been much employed for the treatment of gout and rheumatic conditions. They increase excretion of uric acid but sometimes even in small doses, such as grs. 5 three times daily for a week, they have a powerful toxic action on the liver, and fatal toxic jaundice has resulted. The use of these quinoline derivatives should be limited to carefully chosen cases, and their purchase by the public except under a medical prescription should be prohibited. Other allergic manifestations of the quinoline derivatives are nausea, vomiting, skin rashes, hepatic discomfort, and slight icterus.

Dekrysil is dinitrocresol, a drug recently put on the market in this country, and is similar to dinitrophenol which has been extensively used in America. Both increase the basal metabolic rate and indirectly cause loss of weight or "slimming." They are such powerful poisons to the liver and kidney cells that they should be withdrawn from the list of therapeutic remedies.

Coal-tar derivatives.—The human body seems to have a natural aversion to many of these, and to prefer similar compounds when produced by nature's processes. Thus in the early use of salicylates the natural product was commonly prescribed in place of the derivative from coal-tar; but the purity of the artificial products has been so perfected that there is now little if any difference between the two. It was formerly stated that the higher derivatives of the coal-tar or aromatic compounds were less toxic than the lower ones. This statement is true as regards corrosive action on the mucous membranes, but not as regards toxic action on the liver and kidneys. Some of the higher derivatives, such as the quinoline group, are powerful liver poisons, and others might be cited which have a much more toxic action in this respect than is supposed. It is interesting to note that complex aromatic compounds of vegetable origin such as quinine, cinchonine, and quinidine, have comparatively little toxic action on the liver and kidneys. Quinidine and its salts when introduced were regarded as dangerous toxic drugs, but experience has shown that their careful use is not attended with toxic manifestations.

Thallium acetate is another drug of such powerful toxic action that its use in medicine would be wisely abandoned.

Nirvanol, an organic preparation introduced a few years ago for the treatment of chorea, produces such toxic effects that the remedy may be worse than the disease. It is little employed at the present time in this country.

Aspirin is one of the most valuable and safe of simple remedies. Certain persons have an idiosyncrasy to it, as shown by tachycardia, urticaria, or digestive disturbances, and by these it should be avoided. Phenacetin and phenazone may be classed with aspirin as regards their uses and dangers.

Amidopyrin (Pyramidon) has been largely used, and is in most cases non-toxic. Recently a number of cases of agranulocytosis following its use have been reported, so that the indiscriminate purchase by the public is undesirable. Agranulocytosis has been found to follow the taking of barbituric acid derivatives in several reported cases.

Basal Anæsthetics.—The aim of these drugs is to produce a light anæsthesia of short duration, or a condition of mild narcosis and amnesia so that a much smaller amount of a general anæsthetic will be required. Avertin is in experienced hands perhaps the safest of them, and is especially useful in cases of highly nervous temperament (e.g., in hyperthyroidism). It must be remembered, however, that it belongs to the halogen group of the paraffin hydrocarbons, and has toxic effects similar to those of chloroform. In other words, it has a toxic action on the liver. Where hypohepatism exists it either should not be used or should be given in much reduced dosage. For example, in gall-bladder operations a half dose will produce a definite amnesia and enable the operation to be carried out under gas-and-oxygen with safety. Evipan intravenously produces a short and light anæsthesia, and is useful if contra-indications be carefully considered. Nembutal, Amytal, and Pernocton, given by mouth, have been extensively used, but should be avoided if there are indications of any allergic condition or idiosyncrasy. In hyperthyroidism a dangerous susceptibility may occur. Suppression of urine has also followed administration of this group of drugs as basal anæsthetics, and care must be taken that the kidney function is normal.

Basal anæsthesia has found a useful place in modern therapeutics, but the toxic action of the drugs employed calls for careful investigations into the possibility of any special susceptibility to their effect.

Hypnotic Drugs.—In mild cases of insomnia where drugs are needed it is well to be content with the simple non-toxic hypnotics whose action is well known. The sulphonal group of drugs, such as sulphonal, trional, tetronal, are effective hypnotics, but their slow absorption and delayed action has caused them to be replaced by more rapidly acting hypnotics such as the barbituric acid derivatives. The sulphonal group are toxic, and if given daily over long periods may by their delayed absorption give rise to cumulative effects and serious poisoning. At the present time their use is largely confined to asylum practice.

The barbituric acid derivatives are powerful hypnotics with rapid and certain action. During recent years they have perhaps been the most commonly employed of all hypnotics in cases of severe insomnia, and at least thirty are in use to-day. Because of their effective hypnotic action the margin between the therapeutic and toxic dose is small. The risk of habit formation or addiction is well known, though it is readily admitted that the addiction habit from these drugs cannot be compared with that of morphine, heroin, or cocaine for its compelling power on the patient, nor does the withholding of the barbituric acid drugs give rise to the serious withdrawal symptoms as in the case of morphine addiction. By their modification in constitution the barbiturates not only have the narcotic action of veronal but may have a toxic action on the lungs, kidneys, liver, and heart, as has been illustrated by many recent fatalities. The danger of death from self-overdosage is too well known to need emphasis. The insomnic patient is too often suffering from psychical pain and misery, whether due to his mental illness or perhaps the depression following a too long continued use of these drugs. Can it be wondered that he takes an overdose not caring what happens, and perhaps "hoping for the worst." It is well known that these drugs cause amnesia, and if the tablets are at hand in sufficient quantity repeated doses may be taken unconsciously, and so a fatal dose be taken unknowingly. All of these considerations point to care in the prescribing of barbituric acid derivatives, and to the essential need that they should only be taken under medical supervision by prescription and not be purchased indiscriminately by the public.

In conclusion, it may be said that toxic drugs place in the hands of the medical profession very powerful weapons for beneficent therapeutic use, but their employment must be tempered with knowledge and experience of their action, and careful investigations as to their safety in prescription for any particular case.

ROYAL SOCIETY OF MEDICINE

SECTION OF SURGERY, SUBSECTION PROCTOLOGY

AT a meeting of this subsection on May 8th, Mr. ERNEST MILES, its president, being in the chair, a discussion on the

Conservative Surgery of Carcinoma of the Rectum

was opened by Prof. G. GREY TURNER. He desired, he said, to make it clear at the outset that he was not an advocate of conservative operations for malignant rectal conditions to the exclusion of other methods of treatment. He fully realised the responsibility of advocating a limited operation in the relatively few instances in which surgical aid was sought early. The subject was (to quote the words of one authority) "provocative of consideration." It might be possible in some cases, he thought, to do something between the cuff resection of Angus and the more radical procedures. For some time he had done a cuff resection, the cut being made inside the levator ani, finishing with an end-to-end anastomosis. In this operation he took away everything inside the levatores ani, including the perirectal tissues. Of 19 cases so treated one died a few weeks after operation from general deterioration following renal insufficiency, one died eight months after from general dissemination, six succumbed to actual recurrence, three died without recurrence, and the remainder were still alive and well. After this operation convalescence was rarely a cause of anxiety. One man left the hospital three weeks after operation perfectly healed and with his rectal continence restored. By periodical inquiry he had kept in touch with his cases. In 1931 analysis showed that the sensation of the rectum was normal in 9 of 10 cases, in 9 there was adequate retention of flatus, in 1 the retention of flatus was not so good, and in that case the sphincter was divided to the anus. Most of the patients could retain their evacuations in diarrhœa as in normal times, and most of the ten possessed normal capacity for straining. In 17 cases the condition of the sphincter was assessed. It was perfect in 9, adequate in 7, and incompetent in 1, a man who had sarcoma of the rectum with early recurrence. Looking at the condition of the scar in the rectum afterwards, in seven of the cases there was little indication of any incision. The scar did not appear to interfere with the functions of the rectum. One effect of the operation was to straighten out the rectum and leave it without an ampulla. He did not cut through the bone, but disarticulated the coccyx; the operator should, he thought, not be embarrassed by an undue desire to save bone. For the anterior wall mattress sutures should be used. After completing the anastomosis he placed tissue drains into the cellular tissue, and the muscles were repaired by interrupted catgut sutures. In most cases he did not carry out a preliminary colotomy; in 4 it was done as a preliminary, in 11 it was not done, though in 2 it was needed later. Analysis of 14 cases of fæcal fistula showed that this healed in one month in 2, in three months in 10; 1 healed only after colotomy, 1 did not heal at all. For papilloma in a premalignant stage the cuff operation seemed to be admirably suited; some forms of stricture were also suitable for it. He had no use for resection over a tube.

Mr. H. H. **Rayner** (Manchester) described the conservative operation for growth in the upper third of the rectum, below the pelvi-rectal junction, the lower edge of which was readily accessible to simple digital examination. This operation was conservative only in the sense that the sphincteric mechanism of the anal canal was preserved for the restoration of a functioning anus. If such a procedure could be shown to offer a fair freedom from risk, with prospect of survival equal to that of the established operations, it might, he thought, be regarded as a real advance. The upper end of the rectum was a common site for growths. If it was surgically legitimate to perform a perineal excision for ordinary ampullary carcinoma, with its necessarily restricted removal of bowel and mesenteric tissues above the growth, it was, he suggested, also legitimate, when removing the rectum for high carcinoma, to preserve the musculature of the anal canal. While the risk of this operation to life was somewhat higher than that of a purely perineal operation, the risk was not greater than that of the abdomino-perineal operation. The so-called anterior resection of the rectum left the patient with an intact but functionless anal canal, and could only be justified on grounds of expediency.

The operation he was describing was introduced by Sebrecht of Bruges. It was done in two stages at the same sitting. The first was exactly like the abdominal stage of the abdomino-perineal operation, with the fundamental difference that the pelvic colon was not divided, but a suitable point was selected, usually in its lower third, for later implantation at the anal orifice. The surgeon must satisfy himself that the colon above was sufficiently long and mobile to allow of this point being brought down to the anus without undue tension, and that the blood-supply for the future anus was adequate. The mesocolon was then divided at this point from the bowel to its root, the superior hæmorrhoidal vessels being ligatured. The rectum was freed on all sides below the pelvic peritoneum, so as to facilitate the second stage of the operation. The peritoneal floor of the pelvis was then reconstructed, a gap being left in its centre through which the lower pelvic colon was passed. The edges of this gap were sutured to a point on the pelvic colon as high as possible above the area selected for the new anal orifice. The abdomen was closed without drainage, and the patient placed in a tilted lithotomy position; the lower rectum was washed out, to clear it of debris following the manipulations, and firmly packed with gauze. Next the anal orifice was closed by a purse-string suture, the ends being left long for subsequent traction.

A circular cut was then made round the anal orifice at the muco-cutaneous junction, and the mucous membrane of the anal canal dissected up as a cylinder to a height of about 2 in., special care being exercised to prevent button-holing. A cut was made backwards at the level of the anorectal ring through the muscular walls of the rectum until the subperitoneal space of the pelvic cavity was entered, thus establishing communication with the previous field of operation. The structures still holding the rectum laterally and in front were divided, and the lower rectum being freed, the bowel was drawn down through the sphincters.

Mr. Rayner said he had performed the operation for intrinsic carcinoma of the rectum on four patients. One of them, a woman aged 66, on whom he operated in unaccustomed surroundings, died as a result of the operation. The other three recovered. One man died 20 months afterwards with what the neurologist described as true progressive bulbar paralysis, there being up to death no sign of metastasis or local recurrence. Both the others (women) were still in good health three years and eight months after operation respectively. Both patients had gained in weight.

Mr. W. B. **Gabriel** agreed that occasional cases of carcinoma of the rectum could be cured by local excision; the crux lay in the selection of suitable cases. After a careful review of cases at St. Mark's Hospital, he considered the only cases suitable for conservative resection in the manner carried out by Prof. Grey Turner were those which came into the "A" group of Dr. Cuthbert Duke's classification. Of 142 cases submitted to operation only 16 (11 per cent.) were considered suitable for local treatment. Of a large number of rectal cancer cases only some 5 per cent. fell into group "A." Conservative resection should be reserved for cases in which colostomy was refused or there was some difficulty in the patient's mental or economic position. Cancers were frequently double, polypi had a cancerous tendency; by a more thorough operation the surgeon knew he was reducing the risk of another cancer forming in vulnerable tissue. By the conservative method it was technically difficult to mobilise the entire rectum, especially the anterior wall, and bring it down to make a good anastomosis. A third reason against it was the difficulty in assessing the depth of the spread.

Sir **Charles Gordon-Watson** said he rarely encountered cases at such an early stage that conservative or local operation could be reasonably considered. It must never be forgotten that one was dealing with a potentially malignant rectum; the local operation meant removing only part of the malignant area.

Mr. J. P. **Lockhart-Mummery** suggested that the history of proctology ran in circles. The operation now described by Prof. Grey Turner was done 25 years ago, but with improvements in technique, preparation, and anæsthesia results might now be better. He had used the local operation for stricture and for adenoma. In recent years he had not returned to it for carcinoma as there was a 40 per cent. risk of recurrence. In the operation described by Mr. Rayner the piece of bowel brought down was liable to slough, however carefully the operator might think he had preserved the blood-supply.

Mr. CYRIL NORBURY related a case in a girl, aged 18, of villous papilloma, probably premalignant, on whom he did a cuff resection with end-to-end anastomosis, but without preliminary colostomy. Later he had to do a perineal excision of the rectum.

Dr. CUTHBERT DUKES said there were two schools of thought among surgeons each of which sought the views of pathologists in their support. He would suggest two useful generalisations. Cancer of the rectum remained a local disease until it spread by direct continuity into the perirectal tissues, and there was a fairly long period before this spread occurred. When a surgeon tried to estimate how far a growth had spread by direct continuity, he was apt to under-estimate that spread, as shown by subsequent microscopy.

Mr. W. TURNER WARWICK described a method by which, when doing local resection, the sphincter could be preserved.

In reply, Prof. GREY TURNER said that the number of cases suitable for the conservative operation was likely always to be a small proportion, perhaps not more than 3 per cent. With greater facilities for examination and improved technique he hoped it could be increased.

Mr. RAYNER agreed with the view that recent advances led to better results from less drastic procedures. His own results from the operation he had described for high rectal carcinoma had been so good that he intended to continue.

REVIEWS AND NOTICES OF BOOKS

Problems of Anæsthesia in General Practice

By D. H. LUKIS, M.D. London: Hodder and Stoughton. 1935. Pp. 158. 7*s*. 6*d*.

THIS is a thoroughly sensible little book which, in essay form, was awarded the Sir Charles Hastings prize of the British Medical Association. Almost every page gives evidence of the sound judgment of the writer, and every doctor whose duties include an occasional administration of an anæsthetic should read it. Dr. Lukis ignores no difficulty with which the general practitioner may have to cope when he is required to give an anæsthetic, and points unerringly to the best way out of every dilemma which she describes. Moreover, she defines clearly the circumstances in which the giving of an anæsthetic should be left to an expert. Having defined the characteristics of an ideal anæsthetic and some of the special difficulties of general practice, she proceeds to discuss the estimation of anæsthetic risks, the choice of anæsthetic, and the problems presented in special operations, in preparation of patients and of administration, improvisations and substitutes, and post-anæsthetic conditions.

The sections in the book which deal with the urgent and trying behaviour of patients under anæsthesia could be read with profit by specialists, but for the most part it is with the problems of the occasional anæsthetist that she is concerned. The specialist nowadays has to be more or less familiar with all methods and is little hampered by questions of expense and portability; the practitioner's position in these respects is far otherwise. He is shown here how to use to best advantage the apparatus and the skill that are likely to be in his possession. Dr. Lukis gives a list of what he should carry; this does not include nitrous oxide, but he must be prepared to use this gas where it is provided, whenever the case is deemed suitable. Magill's nasal tubes are part of the routine outfit suggested, and Dr. Lukis strongly recommends the practitioner to familiarise himself with their use. Generally speaking, in common with most of her colleagues, she has found that induction by CE mixture followed by open ether is the most valuable routine method. She is fully alive to all the latest introductions in anæsthetic administration, and shows logically where they fail to earn the reliance of the general practitioner anæsthetist. She gives reasons for her view that avertin is essentially a specialist's anæsthetic; evipan, however, she regards as a valuable agent in many situations in which the practitioner may find himself.

The author's sympathetic regard for the patient's point of view is manifested by her analysis of the nature of pre-anæsthetic fears in 400 consecutive patients; of these the fear of (*a*) never waking up, (*b*) choking or suffocation, and (*c*) feeling pain are the most common, each accounting for some 20 per cent. of the cases. The fear of (*d*) the theatre, surgeon, and of instruments is, in Dr. Lukis's view, somewhat exaggerated by advocates of rectal and intravenous anæsthesia; in her series some 12 per cent. experienced—or confessed—to it. Of the rest, 9 per cent. had a horror of (*e*) making fools of themselves, 7 per cent. disliked (*f*) the idea of losing consciousness, 6 per cent. dreaded (*g*) post-anæsthetic complications, and 1 per cent. (*h*) admitted no fear. The author notes that three of the four patients in this last group showed a definitely exaggerated excitement stage, indicating that their fears were probably repressed rather than absent. These figures are given merely to illustrate the fact that one patient's ideal anæsthetic may be another's bête noir, and other things being equal Dr. Lukis would give local anæsthesia to groups (*a*) and (*f*) and make a special effort to avoid it in group (*c*); non-inhalational anæsthesia or premedication is called for in group (*b*) and contra-indicated in group (*e*). Dr. Lukis, in common with many anæsthetists, clings to status lymphaticus as an entity and does less than justice to the pathologists whose denial of its existence follows logically on the demonstration of the remarkable variations in size of the thymus gland in normal subjects.

The book is written in a crisp and pleasant style with apposite case-notes. The practitioner's point of view is always remembered. He is urged to make certain, before attempting to give an anæsthetic, that he has the confidence of the three important persons concerned—the patient, the surgeon, and himself. If the first and the last are satisfied of his competence, the surgeon remains for consideration. Dr. Lukis's attitude to this delicate problem in professional relations may best be given in her own brisk words, addressed to the anæsthetist—"the surgeon has a hard and exacting job and it is not fair to add any additional burden. Your duty to him is to provide him with a specialist anæsthetist if he shows signs of wanting one. Should he do it too often, examine your anæsthetic technique, and, if it satisfies you, change your surgeon."

The Single Woman

By ROBERT LATOU DICKINSON, M.D., and LAURA BEAM. London: Williams and Norgate Ltd., and Baillière, Tindall and Cox. 1934. Pp. 469. 21s.

THIS book is based on a study of 1078 case records of single women who were treated as patients by Dr. Dickinson. The authors regard it as a continuation of an earlier work, a study of a thousand marriages (see THE LANCET, 1932, ii., 523), and desire that it should be read in conjunction with the topographical atlas of human anatomy noticed in our columns on April 20th last. The book now under review has much the same merits and defects as the study of married women. Dr. Dickinson is a close and accurate observer, whose artistic gifts are now almost as well known to the medical public of this country as to Americans. His most valuable and distinctive contribution to medicine is the correlation which he discerns between the sex life of the woman and her genitalia. In his words, " the female organs of generation, especially the external, largely document the sex life." The relation is stressed in the numerous and interesting case-histories contained in this book, and in the drawings of the topographical atlas.

The average age of the women in the present series is 26, their educational opportunities rather above the average, their health rather below. Venereal disease and pregnancy occurred three and four times respectively in every hundred women. The length of time during which they were observed averaged a year—considerably less than in the series of married women. One in five patients had practised what the author calls " auto-erotism," and there were 28 recorded cases of homosexuality of whom all but 2 ended with heterosexual experiences. An interesting feature of the book is Dr. Dickinson's analysis of the changes in social outlook, dress, and sexual habit which have taken place since the year 1893. The articles of apparel customarily worn by women in that year are shown in a diagram. Five bands were worn round the waist, and it is estimated that all the layers fastened end to end would make a bandage 34 ft. long, the circumference of the waist being taken as 24 in.

Even more apparent than in previous books are the defects of Dr. Dickinson's literary style. These fortunately do not affect his case-histories which read easily and pleasantly; they particularly relate to his summaries, deductions, and conclusions. It is no exaggeration to say that some of these are unintelligible. An interesting chapter on virginity begins with the statement "The bystander becomes virgin again when he lights a candle before the Virgin's shrine." What does this mean? In a chapter on the engagement occurs the following passage: "A professional woman 27 years old is a state of mind. Three or four years' preparation for self-support accepts a discipline which presents other than instinctive values. Choice of a profession is a choice against marriage in so far as it removes uniqueness and places marriage among alternatives." Dr. Dickinson would perform a very welcome service to his many loyal readers if he would write grammatically, observe the elementary rules of punctuation, and refrain from stating his conclusions in poetic or mystical language.

The findings of this series must not be taken as typical of the average unmarried woman, for they are based upon selected material. The women here considered became subjects for investigation by reason of their having attended a gynæcologist for treatment of some dilemma in his province. Nevertheless, the study has much general as well as medical interest.

The Vitamin B Requirement of Man

By GEORGE R. COWGILL, Ph.D., Associate Professor of Physiological Chemistry in Yale University. Published for the Institute of Human Relations by Yale University Press. London: Humphrey Milford, Oxford University Press. 1934. Pp. 261. 18s.

IN 1923 Prof. Cowgill conceived the idea of seeking to ascertain how the vitamin B (B_1) requirements of man and some of the lower animals differed, and whether any discoverable general principle underlay the mode of their differing. This book gives an account of his researches in the ensuing years and of the conclusions which he reached. A single preparation of dried yeast was used throughout as source of the antineuritic vitamin B_1, and in terms of this, the quantitative requirements of the dog, rat, mouse, and pigeon were ascertained. From these results a general formula was established, relating the vitamin requirement to the body-weight and metabolism of the species. Attempts are made to ascertain whether this formula would hold good for the human species. For this purpose, the vitamin B_1 values of a great number of foodstuffs are collected from various sources into a Table (Table 21), where they are expressed in terms of the author's special preparation of dried yeast. These values are then applied to the estimation of the vitamin B_1 values of human diets on which beri-beri is known to have, or not to have, occurred. As a result, the incidence of beri-beri on these diets is shown to be not just inversely proportional to the vitamin B_1 intake, but to be influenced, in addition, by the relative calorie intake and body-weight, in accordance with the author's formula. In short, the formula works when it is practically applied, in that it harmonises data which are otherwise somewhat conflicting. On page 105 the author gives a factor by which the vitamin B_1 value of foodstuffs, expressed in terms of his yeast preparation, can be converted into international units; this makes the values for the various foodstuffs, collected in Table 21 much more universally useful. A bibliography and good table of contents is supplied but no subject index.

Methodik der Vitaminforschung

By CHRISTIAN BOMSKOV, Ph.D., Chemiker an der Universitätskinderklinik, Kiel. Leipzig: Georg Thieme. 1935. Pp. 301. RM.24.

Dr. Bomskov's book is an encyclopædic work on the biological, physical, and chemical methods of estimating vitamins. It contains a vast amount of useful material but this is not critically handled, so that the reader, though practically certain to find the details of any method he is seeking, does not receive much guidance in selecting a method if his mind is not already made up. The international standard preparations and units are mentioned, but might well have received more attention. The indispensable necessity of making a *simultaneous* test with the standard, in every biological vitamin assay which makes any claim to accuracy does not seem to be fully appreciated by the author. An index and a very full table of contents make it easy to find any reference required.

THE LANCET

LONDON: SATURDAY, MAY 18, 1935

THE MEDICAL CURRICULUM

Some four years ago the Board of the Faculty of Medicine of the University of London had under consideration a number of requests from various sources for modifications in the medical curriculum. This circumstance brought to a head the feeling in all medical faculties and institutions that the existing course of medical study required modification chiefly in the direction of making the work of the student less complicated while ensuring continuity in study—a welding both of what had been learnt with what was being learnt and of laboratory training with pathological study. The London faculty, aware of the dissatisfaction existent in other universities, and already officially expressed at Cambridge by certain changes in the educational curriculum, invited that University, the University of Oxford, and the English Royal Colleges to a conference "to consider the defects of the medical curriculum and to make suggestions for reform." The invitations having been accepted, a representative membership was constituted, one of whose first actions was to invite the coöperation of the Society of Apothecaries of London. The Medical Curriculum Conference elected Lord Dawson of Penn chairman; the members of the conference were named on their appointment in The Lancet (1932, ii., 1283), and were recognised as an authoritative body. They got to work about two years ago, and the report which is issued this week shows how industriously they have discharged their difficult task.

The conference recognise that the object of the medical curriculum in general should be to give the student of average ability such knowledge and such education as will enable him to approach and enter practice with some confidence and with a legitimate hope that "his scientific outlook on health and disease should enable him to learn from subsequent observations and experience." The idea that the newly qualified man has completed his medical education being thus pleasantly contradicted, it was held that the curriculum should be designed to make him a safe adviser, though State registration as a doctor cannot transform him into an accomplished therapeutist. The multiplicity of special courses of instruction followed by examinations are found to interfere with just that sequence in study which is desired, while the memorising of details in connexion with special branches occupies time which could better be employed by the student along wider lines. Reform in these directions forms the subject of the main recommendations, and how they can be carried into effect is indicated by the body of the report, in which the time occupied in premedical studies, the intermediate studies, and the actual clinical work is considered in detail. Recognising that the general education of the intending medical student is of the first importance in the framing of a curriculum, the conference took evidence from the obvious sources, and it was to the effect that the education of the advanced schoolboy need not be neglected during preparation for preliminary science examinations; but they came to the conclusion that, in order to allow sufficient time for general education and to avoid the danger of too early specialisation, medical studies proper should not be begun before the age of eighteen. On the difficult subject of the intermediate studies the report is admirable. While not recommending that any change should be made in the present arrangement, whereby the first two years of the medical curriculum are devoted to the study of anatomy and physiology, they suggest methods of rearrangement, relying on concerted action among the teachers, so as to construct a course which should be "more harmonious, consecutive, and interesting." They consider that the work of the student during the intermediate period should be arranged by a board of teachers representing anatomy, physiology, chemistry, biochemistry, pharmacology and pathology, and they indicate how modifications could be introduced, which are summarised in the final recommendations. The activities of such a board, intent on demonstrating to students the close inter-relation of the separate facts to be mastered and the large amount of common ground to be worked over, should be fundamentally valuable.

Two *brief statements* will be received by students and teachers alike with gratitude. The conference hold that in the past too much time has been spent and too great a stress has been laid on memorisation of the structure and details in anatomy for examination purposes; and of physiology it is stated that while coöperation with the clinical staff of the teaching hospital to which the school is attached may prove essential, the student at this stage should not be receiving actual instruction in medicine but rather learning how his physiological equipment ought to be interpreted in terms of therapeutics. The heads of physiology departments, the conference suggest, should have access to patients and be able to enlist the services of members of the clinical staff to give appropriate demonstrations; but the student at such demonstrations should be shown patients not as examples of disease, however typical, but as examples of deranged function. These words face the difficulties inherent in prescribing a curriculum, in which duly proportional opportunities should be given to the acquirement of facts and to the employment of the lessons learned. For such joint demonstrations would introduce the student to that all-important side of his future calling, the consideration of the patient as a fellow creature rather than as a case. That the student is himself alive to this aspect of his training is evident from a discussion on a later page of this issue. The report is a wise one and its presentation excellent.

ÆTIOLOGY OF ACUTE RHEUMATISM

DURING the past thirty years there have been many attempts to discover the causal agent of acute rheumatism. The great majority of these have ended in incriminating the streptococcus. No one would deny that the streptococcus is in some way concerned with the pathogenesis of this disease; the constancy with which streptococcal tonsillitis or pharyngitis precedes acute rheumatism is sufficient evidence of this. But there are grounds for doubting that the streptococcus is the prime cause. First of all there is the fact that all three main types of streptococci have in turn found favour as ætiological agent. The "micrococcus rheumaticus" of POYNTON and PAINE was in all probability *S. viridans;* BIRKHAUGH favoured the non-hæmolytic streptococcus; and the last few years has seen *S. hæmolyticus* given pride of place. And then there is the histological evidence that tells us that the tissues of man react to the "virus" of acute rheumatism in a quite specific manner, giving a type of lesion not found in other streptococcal infections and not capable of reproduction in the tissues of other animals by the various "rheumatic" streptococci. All this makes it questionable whether the streptococcus is the whole story, and in our last issue Drs. SCHLESINGER, SIGNY, and PAYNE, of Great Ormond-street Hospital, who have hitherto been at one with COBURN in considering the hæmolytic streptococcus as the prime cause of acute rheumatism, give other reasons for thinking this view unsatisfactory.

The idea that acute rheumatism is a virus disease is not a new one, and unsuccessful attempts have been made to demonstrate this theory of its origin. Very suggestive evidence in its favour, however, is brought forward this week by SCHLESINGER and SIGNY, now collaborating with Dr. RUSSELL AMIES of the Lister Institute. The means whereby the viruses of psittacosis and vaccinia were identified with the minute bodies seen in stained preparations of virulent material have been adapted to the present investigation, and pericardial and pleural fluids from cases of acute rheumatism have been submitted to fractional and high-speed centrifugation in an endeavour to find out whether these exudates contained demonstrable virus particles. Pericardial fluid from 7 cases was examined in this way and in the deposit obtained from 6 of them particles were seen which, from their uniformity in size and from their appearance in stained preparations and when viewed by dark-ground illumination, were thought to be virus particles. The 6 fluids which gave this positive finding were all from acute cases in the second or third week of the disease; the remaining sample in which no such bodies were found came from a chronic case of some months' standing. Mr. J. E. BARNARD has examined these bodies by the special methods which he has devised and applied so fruitfully in the study of other viruses; and although he hesitates to state definitely that the particles represent a virus he thinks that in all probability they do. But SCHLESINGER and his colleagues have carried the investigation a stage further: for they have also shown that formolised suspensions of the bodies obtained from the pericardial fluid are agglutinated specifically by the sera of patients suffering from acute rheumatism. This part of the work has been carried out by Dr. AMIES, whose investigation of the viruses of variola-vaccinia, zoster, and varicella has made him thoroughly familiar with the difficulties and pitfalls of such inquiries. The experiments have been fully controlled and the agglutination of these bodies appears to be specific.

Does this mean that the virus ætiology of acute rheumatism is established? The investigators are careful to point out that they regard their findings as no more than suggestive. A good deal more requires to be done and in particular renewed attempts to reproduce the disease in experimental animals will have to be undertaken. But supposing that acute rheumatism were known definitely to be due to a virus, would one be in a better position to combat it? That is no easy question to answer. If the causal agent of rheumatism is a virus, then obviously it is one of those, like herpes, which, when it invades the tissues of man, does not incite a solid immunity but leads to what one might term a state of armed neutrality. This delicately adjusted balance of power between host and invader is readily upset by such factors as intercurrent infection, with unfortunate results for the host. Whether or not in virus infections of this type one can by specific means weight this balance more definitely in the host's favour is as yet uncertain. To attempt to predict the possibility of achieving this in acute rheumatism would merely land us in the realm of conjecture.

THE DURATION OF LIFE

THE Registrar-General and those who quote him are not the only students of the duration of life and the causes of death. The experimental biologist collects statistics from controlled communities—"cohorts" is the technical term—of flies, slugs, fish, and such creatures, and asks the question "why do they die?" A recent paper[1] from RAYMOND PEARL's laboratory illustrates one method of treating these statistics. The survival-rates per 1000 initial members of a cohort are plotted against time and different species are found to yield different curves. In the first type nearly all the individuals survive to a certain age and then die off within a short time; either they all run down together like a batch of similar clocks, or they all explode together like a batch of bombs with time-fuses, or they are all destroyed together by an outside agency. Such a curve is found for the wheel-animalcule proales, which would appear to be constitutionally either a clock or a bomb, and it can be obtained from a cohort of flies if they are subjected to starvation—an outside agency. In another type of curve a steady mortality-rate reduces the cohort progressively from youth to old age, until a mere handful remain; the age of the individual per se has nothing to do with the probability of its dying. From that it is argued that the predominating cause of death is not constitutional, but environmental and accidental; so many individuals per centum are destroyed every day by what the authors call "major catastrophic environmental stoppages of the individual life." An approximation to this type of curve is found in certain aquatic organisms (hydra), which also have the characteristic of continuous growth; they never grow old, they just grow bigger till they are accidentally killed. A third group of curves is intermediate between those two types, and includes the mouse, the roach, and wild drosophila. The human curve, which is less simple than those studied in laboratories, probably belongs here too.

---

[1] Pearl, R., and Miner, J. R.: Quart. Rev. of Biol., 1935, x., 60.

From these curves, and kindred data, an attempt is made to deduce the factors determining the occurrence of natural death, and its distribution in time (age). Five of them emerge: (1) endogenous senescence, or the running down of the clock; (2) exogenous senescence, or the accumulating effect of the wear and tear of life, the "environmental buffetings"; (3) the genetic constitution of the individual—whether he is a "Ford" or a "Rolls"; (4) the rate of living, which is taken to include all the functional activities of the organism; and (5) the risk of immediately lethal accidents. These five factors may be simplified to three—namely, genetic constitution, activity (in the broadest biological sense of the term), and environment. In other words, and applied to the human species, this means that a man may live long because he has a strong constitution and can withstand a severe environmental buffeting and a high rate of living, or alternatively because he lives a gentle sheltered life that spares his poor constitution—always provided he escapes death by accident in his youth or his prime. Such a conclusion, to the observer of mankind, would seem quite obvious and not at all new, but it is most interesting to find it emerging even imperfectly from a mathematical study of the vital statistics of slugs and flies.

ANNOTATIONS

BRITISH POSTGRADUATE MEDICAL SCHOOL

ON Monday last the King, who was accompanied by the Queen, declared open the British Postgraduate Medical School. His Majesty was received by Sir Austen Chamberlain, chairman of the governing body, and Lord Snell, chairman of the London County Council, which is coöperating actively with the Government and the University of London in the promotion of the institution.

Sir Austen Chamberlain, in asking His Majesty to approve of the efforts made by those engaged in the creation of the school and to declare the school open, stated the prolonged and laborious inquiry which had led to the practical result. Fourteen years ago, he said, a committee on post-graduate medical education, presided over by Lord Athlone, now chancellor of the University of London, reported that a school attached to a London hospital should be devoted solely to post-graduate education which would be a school for the university and should receive substantial financial assistance from the treasury. These recommendations of Lord Athlone's committee have been exactly carried out and Sir Austen described the tasks now before the school in the following words: "first, to enable medical men in general practice to bring their knowledge up to date, and to familiarise themselves with the latest developments in diagnosis and treatment; secondly, to provide instruction for graduates desiring to pursue special studies in the higher branches of the profession; thirdly, to promote research and to advance medical knowledge." He added that it was the ambition of the directors of the school to make of it a great centre of British medical science, drawing students and teachers alike from all parts of the Dominions for mutual instruction and the promotion of the relief of human suffering.

The King said, in declaring the school open:—

> "It is with great pleasure that the Queen and I have come here to-day to open the British Postgraduate Medical School. The provision within the University of London of a new centre for clinical teaching marks a notable advance in the continuous effort of the medical profession to increase its capacity for service to mankind.
>
> "I am especially glad of this opportunity to show my gratitude for the skill and care which I and my family have received from members of that profession, and not least from distinguished members of the governing body of this school.
>
> "You have reminded me that a foundation such as this was recommended by a committee presided over by Lord Athlone. A recommendation of the same committee resulted some years ago in the creation, with generous assistance from the Rockefeller Foundation, of the great London School of Hygiene and Tropical Medicine. Lord Athlone must be gratified, as Chancellor of the University, to take part in the realisation of the last stage of his far-reaching plan.
>
> "While the two schools trace back to the same origin there is a further bond of union between them. The foundation-stone of each was laid by the Chancellor of the Exchequer, who, as Minister of Health, had so large a share in their evolution, and you, Sir Austen, following a distinguished family tradition, are chairman of each board of governors.
>
> "It is my earnest hope that this school, with its happy union of ward and laboratory, university and local authority, drawing students and teachers alike from all parts of our Empire, and I trust from regions even more widely spread, may prosper under God's blessing. May it play an imperial rôle in the winning and dissemination of medical knowledge, in the relief of suffering among my peoples in this country and overseas, and in enabling the doctors of all lands to come together in a task where all must be allies and helpers."

Following His Majesty's declaration that the school was open, numerous presentations of members of the governing body and others directly concerned in the movement were made by Sir Austen Chamberlain. The King and Queen then made a complete tour of the building, a strenuous task as will be seen by reference to the description published in another column (vide p. 1172). Their Majesties visited the clinical lecture theatre, the library, and the various departments, where the directors were presented to them: Prof. Francis Fraser, director of the department of medicine; Prof. Grey Turner, director of the department of surgery; Prof. James Young, director of the department of obstetrics and gynæcology; and Prof. E. H. Kettle, director of the department of pathology. Each director in turn presented his readers, while among others presented were Mr. Edwin Bax, F.R.I.B.A., the architect, Dr. Duncan White, radiologist of the hospital, Mr. Leslie Clark, Ph.D., physicist to the London County Council, and Sir Thomas Carey Evans, medical superintendent of the hospital.

PROPHYLAXIS AND EXPOSURE IN MEASLES

THAT the results of the sero-prophylaxis of measles may depend upon the conditions under which exposure to infection takes place is emphasised by some observations of Karelitz and Schick.[1] Serum was obtained from five adult immunes. The samples were not pooled but were injected individually in a dose of 6 c.cm. in two groups of susceptible children of comparable ages exposed to measles over similar periods; one group, however, consisted of children in hospital and the other of children in their own homes. It was found that the protection afforded by each sample was much greater in the institutional than in the familial group. The combined groups comprised 134 children. Comparison of the conditions of exposure showed that the protection-rates were 87 and 29 per cent.; the attenuation-rates 13 and 22 per cent.; and the failures 0 per cent. and 49 per cent. in the hospital and familial groups respectively. Similar differences have been reported in the results obtained from convalescent serum by Park and Freeman, and by Levinson and his co-workers, and these are quoted by the authors. The discrepancies in the results are diminished when larger doses of serum are employed in the case of children exposed in their homes. Thus, in further trials, 6 c.cm. of serum in an institutional group produced results closely similar to those already mentioned; but the injection of 8 c.cm. of adult serum in a familial group afforded a protection-rate of 46 per cent., an attenuation-rate of 43 per cent., the failures either to prevent or attenuate dropping to 11 per cent. Still larger doses of from 12–25 c.cm. of adult serum produced correspondingly more favourable results.

Contact in home life is more intimate than in hospital wards where exposure may be very unequal. In hospital some children may escape infection entirely; others be but slightly infected; while others again are infected intensively and repeatedly throughout the period of exposure. Karelitz and Schick observe that the differences in degrees of exposure between familial and hospital groups are accentuated in those hospitals provided with cubicles or where an isolation technique is observed. An analysis of the results obtained from the injection of 6 c.cm. of adult serum in a series of 106 children of from 2 to 6 years of age all exposed to measles for periods of from 2 to 5 days showed that in the case of children whose home conditions were good, the protection- and attenuation-rates were 58 per cent. and 23 per cent., 19 per cent. being failures. Where the home conditions were bad these rates were 0 per cent., 27 per cent., and 73 per cent. respectively, whereas in a hospital group they were practically reversed, protection being attained in 83 per cent. and attenuation in 17 per cent., there being no complete failures. An important factor in maintaining or enhancing the level of immunity to diphtheria amongst those, such as nurses in fever hospitals, who have become Schick-negative as the result of active immunisation is the frequent reception of small doses of infection which by acting as stimuli raise the antitoxic titre of the blood. Karelitz and Schick relate the results of an attempt to increase the immune antisubstances of adults by re-exposing them frequently and intimately to patients during the first few days of severe attacks of measles. Four volunteers were bled *before* and 8 and 21 days *after* the last of thirteen exposures to the disease of from 30 to 60 minutes' duration. Sera obtained before and after reinfection were injected into a large number of young children presumably effectively exposed to measles. When the group of children was considered as a whole the results appeared to be greatly in favour of the samples obtained after reinfection, but on further investigation the same discrepancy between institutional and familial exposures appeared and largely reduced the apparent superiority of the reactivated samples. By increasing the dose of the pre- and post-reactivated samples employed in the case of children exposed at home from 6 c.cm. to 8 c.cm. the advantage in favour of the reactivated samples became inappreciable.

While in institutional epidemics of measles all susceptible children may develop the disease after the first exposure, the authors remark that this occurs far more commonly as the result of successive exposures. This is, of course, quite true, and if it is a question of testing the value of any batch of convalescent or adult immune serum, which is usually pooled, doubtless the more rigorous conditions provided by familial contact are to be preferred as they suggest, but in the testing much valuable serum must be expended. In any case the medical administrator of a sick children's ward must be pragmatic; his main object is to reduce the effects of cross-infection to a minimum. To this end he will segregate the infective patient at the earliest possible moment and without relying unduly upon a past history of attack, only too often a broken reed, use his precious stock of convalescent or adult serum primarily in an attempt to prevent the expected attack amongst children under 3 years of age. If the serum which he has at hand is of attested potency so much the better. Whether the success attained should in part be credited to ineffective exposure is not of great practical importance.

TUBERCULOSIS IN DOMESTIC PETS

WHILST intensive study and attention has long been focused on tuberculosis in cattle, and the importance of the bovine type of infection in causing both abdominal and meningeal lesions in children has been fully recognised, relatively little emphasis has been laid on the possibility of the disease being acquired from domestic animals. Dr. A. Hjärre and Dr. C. W. Herlitz have carried out what may therefore prove to be a fruitful piece of work[1] in investigating a number of cases of associated canine and human infection. They point out that tuberculosis is by no means rare either in cats or dogs, animals which are frequently the intimates both of children and adults. It is difficult to assess the actual incidence of the disease in domestic animals, as the majority die at home without the assistance of a death certificate. Also, the figures obtainable from the various veterinary institutions on the basis of post-mortem examinations performed show considerable differences. Thus in Berlin (1925) the percentage of tuberculous dogs was 0·3, of tuberculous cats 2·0, while the corresponding figures for France (1927) were 5·6 (dogs) and 13·5 (cats). Dogs under two years of age are, however, more frequently found affected than older animals, and the disease is rare in dogs over seven years old. Tuberculosis is commoner in male than in female dogs; sheep dogs, fox-terriers, and airedales appear to be the most susceptible breeds. Hjärre and Herlitz report in detail six cases in which the occurrence of tuberculosis in a human being and in a dog or cat living in the same household suggests more than a coincidental relationship. Notes on two of the cases follow.

[1] Acta pædiat., 1935, xvii., Supp. I., p. 141.

A poodle had lived for seven years in the house of a healthy mistress and had been well throughout this time. From the spring to the autumn of 1932 a woman lived in the household; in May, 1932, she began to cough, and in the following February, 1933, she died with extensive cavitation of the lung and tubercle bacilli in the sputum. She had been very intimate with the poodle, whom she was in the habit of feeding from her own plate. In October, 1932, the dog began to cough, and in November was diagnosed at the veterinary college as suffering from active pulmonary tuberculosis. The diagnosis was confirmed at post-mortem examination in March, 1933.

In January, 1932, a dog who had lived in a household for some years began to cough, lose weight, and become anæmic. A diagnosis of pulmonary tuberculosis was made and confirmed at autopsy when the dog died in May, 1932. Tubercle bacilli in the tracheal secretion were of human type. A month after the dog's death a girl of 14 in the house became affected with erythema nodosum. In this family, however, the mother had suffered from pleurisy in 1930, but had been free from cough and all symptoms since this time.

In three of the cases of animal infection in which the organism was isolated, it was found to be of human type. Whilst it is possible that the tubercle bacillus may become non-virulent to human beings by passage through a dog or cat, the Scandinavian investigations more than suggest the possibility of infection of animals from a human source, and make a case for considering the possibility of human infection from domestic animals. Coöperation of doctors with local veterinary institutions would be valuable.

WORK AND NOISE

INTERFERENCE by noise with the capacity to hear produces a disproportionate mental irritation. Hence a tendency exists a priori to ascribe a maleficent influence to noise—which may be defined as an excess of unwanted sound. When efforts were undertaken by the Industrial Health Research Board[1] to measure this influence, they disclosed that it may readily be exaggerated, if estimated by its effect upon industrial work. Like any other unvarying stimulus, noise produces progressively diminishing effects with continued application; hence discontinuous noise is more disturbing than continuous. Noisy conditions may even become a kind of natural background to work, and a change from noise to silence may disturb performance more than minor changes in the noisy background. Further studies[2] have recently been conducted in weaving sheds where the continuous roar and clatter of power-driven looms constitutes a very definite excess of unwanted sound, amounting to 96 decibels which is a sound intensity entitling it to the term "blare"—corresponding to the term "glare" used in connexion with excessively bright lights. So great is the racket that weavers practise lip-reading in order "to hear themselves speak." Moderate traffic noise, for comparison, has a sound intensity of about 60 decibels, ordinary conversation of about 50. The noise was somewhat deadened experimentally by the use of ear defenders, or plugs placed in the ears, which lessened the sound intensity by 15 decibels—about half the apparent loudness. The new study was spread over a period of 12 months during which accurate records of output were carefully compiled. It strengthens the conclusion previously advanced that excessive noise is by no means a negligible factor in determining industrial efficiency; the performance of normal daily work is definitely handicapped thereby. While weavers may become so accustomed or acclimatised to noise that consciousness of its subjective effects—irritation, annoyance, distraction—ceases or becomes much less acute, yet their personal efficiency was found to be increased by about 7½ per cent. when the noise was subdued by wearing ear defenders. This is an effect of considerable magnitude; moreover, it is not a temporary one, occurring only in the initial stages of exposure to noise; it occurs in individuals who for years have been accustomed to excessive noise at their work. Complete immunity cannot be acquired, unless it be by the development of partial deafness—a cure more troublesome than the trouble. This study proves that it is worth while in the interests of comfort and of production to reduce noise in industry by every possible means, whether by quietening machinery or by palliatives such as ear defenders.

WILHELM KOLLE

THE death on Sunday last of Prof. Wilhelm Kolle, director of the Institute for Experimental Therapy in Frankfurt, removes Germany's outstanding bacteriologist. Kolle was born in the Harz, qualified in 1892, and then for four years assisted Robert Koch at the Institute for Infectious Diseases in Berlin. As an outcome of his position there he was asked by the Cape Government to conduct a scientific expedition in South Africa and by the Egyptian Government to do the same in the Sudan, where he founded a laboratory in Khartum. Thus early he gained the world-wide knowledge of the problems of infectious disease which enabled him to collaborate with Wassermann in the classical Handbook of Pathogenic Micro-organisms which now runs to ten volumes. On leprosy, rinderpest, cholera, and plague Kolle made important individual contributions; he was the first to prepare an effective antiserum to an ultramicroscopic virus (rinderpest), and the simultaneous method of immunisation was due to himself and the late Sir George Turner, formerly M.O.H. for the Transvaal. It was Kolle also who in association with R. Otto evolved the method of immunisation against plague with attenuated cultures, and who with R. Pfeiffer worked out protection against cholera with dead cultures. As Ehrlich's successor at Frankfurt he became director of the Georg Speyerhaus research establishment, and it was he who first produced neosalvarsan. He also worked at a forerunner of stovarsol which Ehrlich had described as "spirocid" and discarded on account of its toxicity. More recent books in which Kolle participated are evidences of his ever restless literary

activity: a handbook of Salvarsan Therapy, a textbook of Clinical Methods of Investigation, and one on Experimental Bacteriology. For a short time he occupied the chair of bacteriology at Berne, but he was not at home outside his Fatherland, and the rest of his life was spent in German University towns.

A CENTURY OF MEDICINE IN BENGAL

We published last week an account by a correspondent of the centenary of Bengal Medical College. In the early days of the British occupation of India the practice of medicine was speculative and empirical, the excellent Arabic and Hindu systems, which had been employed for hundreds of years, having fallen from their high estate. Native medical men were bound by tradition, and the only dissection possible was that performed on animals and at post-mortem examinations. A new era dawned when a government order abolished the Native Medical Institution and, in February, 1835, founded a new college in the converted petty-court jail, to which Assistant-Surgeon M. J. Bramley was appointed superintendent. The breaking of the racial prejudice against dissection was due to Pundit Gupta who, with four courageous pupils, went secretly to an outhouse and with his own hands dissected a body under the direction of Dr. Goodeve, assistant to Dr. Bramley. The first college examination was held, after 3½ years of study, in October, 1838, the curriculum embracing eight medical and allied subjects; midwifery was excepted, for the teaching of which there was no provision. In 1845 the college was recognised as a teaching centre by the Royal College of Surgeons of England, and in the same year Dr. Goodeve sailed with four Indian students destined for higher studies in England, where they proved highly successful. The foundation-stone of the medical college hospital was laid by the Earl of Dalhousie in 1848, the Government making a grant of £50,000 from the lottery fund, a means of raising money which had been suppressed by English public opinion some years before. Marble tablets on the walls of the staircase set out both the Vedic and Hippocratic oaths. Familiar names stand out in this history. Esdaile began to operate in 1845 upon patients under the influence of mesmerism, and published a book in the following year giving his experience of 261 operations. Partridge introduced the bloodless method for scrotal elephantiasis, while O'Brien opened the sac in treating hernia and began the excision method for hydrocele. McLeod journeyed to Edinburgh to see Lister's work, and on his return to India did 13 amputations without a death. The emergencies of the Mutiny led to the employment of female nurses who wore no uniform but carried a fan as a badge of office. There are many other interesting recollections in the centenary volume.

CONGENITAL WORD-BLINDNESS AND READING DISABILITY

Children who find difficulty in learning to read are often brought to child guidance clinics for analysis and treatment and it becomes a matter of importance to discover the physical and psychological factors in the case. S. T. Orton, whose writings on this subject are well known, groups together cases in which others have found differentiating features. An article by Miss K. Duguid in *Guy's Hospital Reports* for January is of value in emphasising these differentiating features and supplying a basis for diagnosis and treatment. Miss Duguid, who is psychometric assistant at the hospital, distinguishes three definite types of reading disability. First congenital word-blindness, as described by Hinshelwood, characterised by the gravity of the symptoms and the inability to interpret words although perception may be perfect. Secondly, visual imperception or malperception, in which there is confusion of letters of similar form and even reversals of small words—e.g., "was" for "saw." Thirdly, the condition of left-eyedness and ocular dominance, on which Orton lays so much emphasis, with a tendency to mirror writing and to reading from right to left. The first group can usually be clearly diagnosed, but the second and third have some features in common. Miss Duguid differentiates a fourth group of reading disability, less specific in type, due probably to a combination of causes, including subnormal intelligence, poor auditory perception, and emotional disturbances. Classification so stated appears simple, but a careful reading of the illustrative cases quoted by Miss Duguid and described in considerable detail demonstrates the extreme complexity presented by diagnosis and the possibility of many factors being responsible for the symptoms of a particular case. That heredity was playing a part is clear in some of the cases, but on the whole environmental factors predominate. The article illustrates the value of one kind of investigation now being carried out by child guidance clinics on behaviour problems. Treatment, Miss Duguid points out, has to vary "in accordance with the particular difficulties, interests, and capacities of the individual"; no one method can be applied all round. It is only by more and more individual study of these children that a clearer understanding of their difficulties can be reached.

A MEDICAL HISTORIAN

The recent death of the distinguished medical historian Fielding Hudson Garrison reminds us that he, perhaps more than any one man, contributed to the rising of a valuable school of medical biography in the United States, the example there set having been followed in all lands. Garrison, who was 64 years of age at the time of his death, interpreted the responsibility of a medical historian in a large way, sometimes by writing individual memoirs, and at others by furnishing accounts of medical progress along different lines, illustrating the narratives by references to particular protagonists. He was thoroughly equipped for the task, as for 33 years, 1899–1922, he was assistant librarian at the Army Medical Library in Washington. During a large part of that period he was co-editor of the Index Medicus, published from the Surgeon General's Library, and editor of the Index from 1912 to 1927, when the publication was affiliated with the Quarterly Cumulative Index of the American Medical Association. Among his best known literary productions is his "Outline of Medical History," which appeared first in 1913, went through more than one edition, and was brought to the notice of the English public by his friend Clifford Allbutt, who always had a high admiration for Garrison's talent. Among the biographies from Garrison's pen may be mentioned in particular a memoir of J. S. Billings, while his more general reviews of the march of medicine include "A History of Endocrine Doctrine" which appeared in 1921, "A History of Pædiatrics" which appeared in the following year, and finally "A History of Military Medicine"; here active service had given him personal knowledge, for he had served in the Philippines with the American Army, and in various training camps in the United States during the late war. Garrison's editing of the Index Medicus proved him to be a prodigious as well as methodical worker, but he found time apart from his official labours to be deeply interested in the arts, and was especially a lover of music. He is a great loss to medical literature.

RUPTURE OF THE RENAL PELVIS

Dr. Benjamin S. Abeshouse has found [1] records of 64 cases of rupture of the pelvis of the kidney and adds 3 from his own clinic. In reviewing the findings, he begins by dividing rupture of the kidney into traumatic and spontaneous. The first may occur either with a congenitally normal kidney or with one severely damaged by inflammation or obstruction. It is usually the result of direct or indirect trauma exerted against the kidney in such a way that the pelvis is jammed against the lower ribs or the transverse processes of the upper lumbar vertebræ. When this happens, the tear is usually linear and radial. Spontaneous rupture, on the other hand, never takes place unless the kidney is already the seat of a chronic pyelonephritic or hydronephrotic process. Rupture here is due to a sudden or gradual alteration in the intrapelvic pressure caused by the addition of an obstructive lesion in the upper or lower urinary tract. Rupture of a pathologically weakened pelvis has also been known to follow instrumentation—e.g., retrograde pyelography. Traumatic rupture is commoner than spontaneous, and as would be expected is seen more frequently in males than females. It is to be suspected if, in a patient with an antecedent history of chronic pyelonephritis or hydronephrosis, there is a sudden sharp pain in the renal region followed by swelling, rigors, pyrexia, vomiting, and (often) collapse. A clinical impression of rupture should always be confirmed by pyelography by the gravity method. Operative treatment may be conservative or radical, but nephrectomy is unjustifiable until the condition of the other kidney has been ascertained. In a patient with much toxæmia or debility the operation should be carried out in two stages, preliminary drainage being followed by nephrectomy or conservative repair at a later date.

ACUTE OPHTHALMIA IN EGYPT

In the eighth annual report [2] of the Giza Memorial Ophthalmic Laboratory, the director, Dr. Rowland P. Wilson, has some interesting remarks to make about the seasonal ophthalmias in Egypt. It appears that the two common forms of acute ophthalmia—namely, Koch-Weeks conjunctivitis and gonococcal conjunctivitis, which he finds from smears to be of about equal frequency—differ materially in the time of their appearance. The former occurs in epidemic form chiefly in the spring, the latter in the autumn, as is well brought out in the graphs which accompany the report. It is easy to explain the coincidence of the Koch-Weeks infection with the onset of the warmer days in the spring, but why is not the increase continuous through the still hotter days of summer? Dr. Wilson finds three grounds for this: (1) excessive heat inhibits the growth of the Koch-Weeks bacillus; (2) its virulence falls after it has reached epidemic character in May and June; (3) the drop in July and August is associated with the decrease in the number of flies. The primary and secondary seasonal maxima of cases coincide with the two definite fly-breeding seasons of the year. The incidence curve of gonococcal conjunctivitis on the other hand depends on two purely climatic factors, temperature and atmospheric humidity. The gonococcus is peculiarly susceptible to desiccation and survives in discharges only so long as these remain moist. In pus it dies as soon as the pus dries. The Koch-Weeks bacillus may be still alive two and a half hours after drying in the open and can withstand drying at room temperatures for at least 18 hours. This explains why gonococcal conjunctivitis is comparatively rare during the dry hot spring, but begins at once to increase when the atmosphere becomes moister. No doubt methods of transmission also play their part in the difference. Direct Koch-Weeks infection by flies has not yet, it seems, been subjected to direct proof, but is now being investigated in the Giza laboratory. Dust is another fruitful source of chronic conjunctivitis and may have some effect in increasing acute cases of the Koch-Weeks variety. The dry desert winds of March and April, while favouring the spread of this form, would inhibit the spread of the gonococcal variety. In Egypt the coincidence of gonococcal urethritis and conjunctival infection is held to be unusual. Urethritis shows no sign of seasonal variation in the figures collected from all the Government venereal centres in Cairo. But does this in itself prove that the two are not related? Ophthalmia neonatorum, as we know it, is uncommon in Egypt.

CHARLES BELL, DISCOVERER

There are men of science along all lines whose original work proves so fundamentally valuable that reference must always be made to it as developments occur, and in this way their personalities, as discoverers, remain ever interesting. Charles Bell laid the foundations of our physiological knowledge of the nervous system, and in the current number of the *Edinburgh Medical Journal* Prof. Edwin Bramwell gives an interesting résumé of his life and work, the occasion being the delivery of the Harveian oration last year before the Royal College of Physicians of Edinburgh. Sir Charles Bell did for the nervous system, Prof. Bramwell claims, what Harvey did for the circulation, Harvey's work, however, being more or less finite, while Bell's opened up a new vista for his successors. Bell left Edinburgh for personal and family reasons when his work was only beginning, and came to London. He had made a mark by collaboration with his brother, John Bell the surgeon, in a system of anatomy, and had there and elsewhere displayed his fine artistic capacity. He had no regular appointment in London and for a time met with no success as a lecturer. But his sterling qualities attracted the attention of those immensely influential seniors Abernethy and Astley Cooper, and the publication of the "Anatomy of Expression" brought him immediate fame. Later he was enabled to purchase the great Windmill-street school, and was appointed surgeon to the Middlesex Hospital. There followed his discoveries in relation to the anatomy of the nervous system culminating in the publication of papers, previously communicated to the Royal Society as a volume, entitled the "Nervous System of the Human Body." This was the first exposition of the function of the nerves. In 1836, being 62 years of age, he accepted an invitation to fill the chair of surgery in Edinburgh, a position which he held until his death from angina pectoris in 1842. Prof. Bramwell's sketch shows Sir Charles Bell to have been an outstanding figure as a physiologist, pathologist, and surgeon, while his accomplishment as artist was of the greatest value to him. Prof. Bramwell shows that Bell's researches were leading him up to the dictum enunciated by Hughlings Jackson many years later that movements not muscles are represented in the cortex. And Prof. Bramwell concludes: "Bell provided a conception of the functioning of the nervous system based upon his anatomical, experimental, and clinical observations which has been proved, by those who have followed him, to be substantially correct. He conceived what may well be described as the circulation of nervous impulses, a discovery of the first magnitude, as was Harvey's discovery of the circulation of the blood." We can never be reminded too often of the debt which medicine owes to such discoverers.

IS CODEINE A DANGEROUS DRUG?

ATTENTION has recently been directed in Canada to the considerable increase in the imports of codeine into that Dominion, and the question has been reopened whether codeine (methyl-morphine) should not be regarded as a "dangerous drug," and be subjected to the same or similar restrictions to those applicable to morphine, heroin, and cocaine. In the *Canadian Medical Association Journal* for April figures are quoted to show that, whereas in 1927 9330 oz. of codeine were imported, in 1934 no less than 46,190 oz. entered the Dominion; and further that while the per-capita consumption of codeine in Great Britain is 11 kilos per million inhabitants, in Canada it is 109 kilos. Moreover, the Department of Narcotics in Ottawa have found reason for thinking that codeine is to some extent replacing morphine among drug-addicts, more especially among the under-world in Canadian cities; it is significant that while in recent years the importations of morphine have fallen considerably those of codeine have increased. The question whether codeine should or should not be regarded and scheduled as a dangerous drug of addiction is not a new one. Indeed, at the first Hague Opium Conference in 1911–12 the question was keenly discussed and in the first draft of the Hague International Opium Convention codeine was in fact included. Its inclusion was strongly resisted by the German delegates who challenged the conference to cite any case of codeine addiction. One of the British delegates (Sir William Collins) promptly cited a case from the *Klinische Wochenschrift* of "Codeinismus," in which the victim had been reported to be taking 70 to 100 codeine pills a day, and referred to the works of Cushing and Sainsbury in support of the opinion that codeine should be regarded as a habit-forming drug. Eventually codeine was struck out of the Convention to secure unanimity, but, as was remarked by the British delegate, "it must not be held that this is done because codeinism and codeine mania are unknown to medical literature." At the present time, under an order in council and by special regulations which came into force on Jan. 1st, 1934, codeine and its salts become drugs under Part III. of the Dangerous Drugs Acts for certain purposes, but are not subject to the regulations which apply to other drugs named in Part III. We understand that the Narcotics Division at Ottawa have placed the information collected in Canada before the Opium Advisory Committee of the League of Nations and that the Health Committee of the League has been requested to report as to whether codeine should or should not be dealt with like other dangerous drugs of addiction.

LATE RESULTS OF CHRONIC APPENDIX OPERATIONS

THE excellent new vogue of following up patients discharged from hospital many years before has recently led Dr. E. Poppe[1] to analyse the 703 patients whose appendices were removed for chronic diseas in a Norwegian public hospital in the five-year period 1928–1932. They had complained of pain in th right iliac fossa, lasting for a couple of minutes t a couple of hours, and often radiating to the righ thigh. Many of them had been dyspeptic and constipated. In spite of a careful clinical examinatio little had been found apart from tenderness in th right iliac fossa. A noteworthy fact was the minority in which the males found themselves among th 703 patients; only 241 (34·3 per cent.) of them wer males. Dr. Poppe has found a similar numerica feminine predominance in the statistics of sever other large public hospitals in Norway. In his own material the age at which his female patients wer most subject to primary chronic appendicitis was between 15 and 30—an age-incidence certainly not explained by Aschoff's pathological-anatomical studies which have shown that post mortem the incidence of diseased appendices rises steadily with age both in women and in men. Another curious fact, to which Dr. Poppe draws attention, is that in his hospital acute, as distinct from chronic, appendicitis is just as common in men as in women. The appendicectomy proved fatal in three cases. A set of questions was addressed to the survivors, and those who reported themselves perfectly fit were not re-examined. As many as 646 were, however, re-examined. In 432 of these cases (66·9 per cent.) the results after the appendicectomy were good. When the patients were classified according to sex, it was found that such good results had been achieved by 84·1 per cent. of the male cases, but only by 58 per cent. of the female cases. This comparatively low percentage for women was reduced still further to 50 per cent. in the case of the women aged about 25 years. A classification, according to sex, of the ailments from which 33 men and 176 women still suffered showed that the numerically most important were constipation, dyspepsia, and nervousness combined. Nine men and 91 women came under this heading. There were as many as 41 women in whom pain in the right abdomen was the only persistent symptom. As a result of this investigation Dr. Poppe has a practical suggestion to make. The number of appendicectomies for so-called chronic appendicitis in women could be reduced if the constipation from which they suffered were properly treated; and the results of the operation when carried out could be improved if attention was paid to constipation in the after-treatment.

THE King has nominated Dr. John Ritchie, medical officer of health for Dumfries, as a member of the General Medical Council. Dr. Ritchie takes the place of the late Sir Leslie Mackenzie as Crown nominee for Scotland.

DR. A. G. W. Thomson has been appointed a commissioner of the General Board of Control for Scotland in succession to the late Dr. J. P. Sturrock.

THE next session of the General Medical Council will open at 2 P.M. on Tuesday, May 28th, under the presidency of Sir Norman Walker.

THE Cambridge University Press will publish shortly an annotated list of medical practitioners in the diocese of London, 1529–1725, licensed under the Act of Parliament 3 Henry VIII., cap. 11. The object of this short book is to show in what manner the Bishops of London handled their great and serious responsibility respecting the licensing of medical practitioners.

PROGNOSIS

A Series of Signed Articles contributed by invitation

LII.—PROGNOSIS OF BRONCHIECTASIS IN CHILDREN

UNTIL the introduction of lipiodol in radiography of the chest by Sicard and Forestier (1922), opinions on the prognosis in bronchiectasis in children were for the most part pessimistic. This is readily understood on reviewing the criteria formerly required for a diagnosis of bronchiectasis on physical signs alone—dullness at the base with bronchial breath-sounds and moist crepitations, chronic cough, worse in the morning with copious muco-purulent sputum, clubbing of the fingers, and cyanosis. Such a picture is uncommon in childhood; it represents merely an advanced state of pulmonary crippling, and the expectation of life of those manifesting such changes could only be unfavourable. From the evidence provided by lipiodol investigations, we now know that bronchiectasis may be present and give rise to very few symptoms, and also that it is a much more common condition in children than was formerly supposed. Bronchial dilatation, in fact, cannot be diagnosed in its early stages without the aid of lipiodol. The prognosis therefore has required revision and tends to be more hopeful, but is still in a stage of determination.

CLINICAL ASPECT OF ACQUIRED BRONCHIECTASIS

The type of case in which bronchial dilatation may be suspected presents clinically the physical signs of pulmonary fibrosis, but these are often so inconspicuous that an examination depending on auscultation and percussion gives little information on the condition of the lung. Of greater significance is the fact that there is almost always a past history of pneumonia (broncho-pneumonia), often associated with measles, whooping-cough, or influenza. The child is brought to the doctor because of a persistent cough in the daytime, which gets worse in winter. The cough is not spasmodic, and is usually unproductive. Sputum, when present, consists of thick tenacious mucus, and only in advanced cases is it purulent and evil-smelling from additional infection with putrefactive organisms. Vomiting provoked by the cough is a suggestive symptom, and in a few cases hæmoptysis has been recorded. The child is often several pounds below the proper weight for its age. Dyspnœa on exertion, cyanosis, and clubbing of the fingers are signs of severe pulmonary involvement in chronic cases.

Physical signs to some degree are usually found to be present when the chest is examined, though they may be slight. They include dullness on percussion at one or both bases, possibly with displacement of the heart towards the most affected side, weak breath sounds but seldom bronchial breathing, and in some cases moist râles. A diminished expansion of the lower part of the chest on the affected side may also be observed.

RADIOGRAPHY AND LIPIODOL

By X rays alone one of two conditions may be revealed: (1) The common form is fibrosis denoted by excessive root shadows and heavy streaky shadows running from the hilum towards the diaphragm. During inspiration the diaphragm on the affected side often does not descend so fully as on the opposite side. (2) Collapse of a lower lobe. In this type of case there is a triangular shadow at one or other base, the spine and diaphragm forming two borders of the triangle, and the visible border or hypotenuse reaching from the hilum to some point along the phrenic surface. With lipiodol injection the presence of bronchiectasis is confirmed or disproved. In either of the two conditions, interstitial pneumonia or lobar collapse, bronchial dilatation is liable to occur. The mechanism of its production is thought to depend chiefly upon inspiratory effort, especially that which follows the act of coughing. With expansion of the chest wall a negative intrathoracic pressure occurs, causing air to enter the alveoli. If this is prevented locally by the accumulation of thick tenacious mucus, the obstructed bronchioles tend to dilate. Other explanations of dilatation are that it is the effect of fibrous traction, which can rarely be proved, or of accumulation of septic sputum in weakened bronchi, which only occurs in the "wet" type of bronchiectasis. The dilatation may be saccular or cylindrical, the latter form being common when there is collapse of a lobe. In this atelectatic type of bronchiectasis the triangular shadow on the spino-phrenic angle represents collapse of the whole of a lower lobe. With lipiodol the outline of a main bronchus can be seen entering the triangular area.

There are three methods of injecting lipiodol (10 to 15 c.cm.): (*a*) the intratracheal route, by direct introduction through a catheter; (*b*) the cricothyroid route, by means of a cannula; and (*c*) through a nasal catheter reaching the trachea. The best and safest method for children is (*a*) the intratracheal route, though this necessitates general anæsthesia by ether, which requires to be fairly deep. Points against (*b*) and (*c*) are, that in (*b*) surgical emphysema of the mediastinum has been known to occur and to prove fatal, and in (*c*) there is uncertainty whether the lipiodol will enter the trachea in sufficient quantity; moreover, to suppress the cough reflex spraying with cocaine will probably be required, and this is a dangerous procedure in children. In (*a*) the amount of discomfort and coughing involved by the injection of the lipiodol is usually slight. The method demands a high degree of technical skill.

The injection of lipiodol is not advocated for every patient presenting signs of pulmonary fibrosis in which bronchial dilatation is suspected, but the accurate information obtained justifies its use in cases requiring prolonged treatment, and especially when it is desired to ascertain the state of the bronchioles in a collapsed lobe.

THE OUTLOOK

The outlook depends upon whether the bronchiectasis remains "dry" with little or no sputum, or becomes "wet" with purulent sputum. Age has some influence. Cases commencing in infancy have a high mortality with a short period of survival. In those with onset at a later period bronchiectasis may be present for many years, even into late adult life without the incidence of sepsis. Cases of recovery have been described, where on subsequent lipiodol examination all traces of bronchial dilatation have disappeared. This result, however, is rare in the atelectatic type of bronchiectasis, in which the collapse is usually permanent. As Anspach has indicated, the smaller and denser the triangular shadow remains, from absence of re-expansion, the worse the prognosis. An unfavourable sign in bronchiectasis is the recurrence of febrile attacks with increase of cough and of physical signs in the chest, signifying renewal of pulmonary inflammation. Infections of the upper respiratory passages, throat, antra, ears, are often mentioned as predisposing to advance of the bronchiectatic process, but in some cases they are probably secondary not primary, arising from infection ascending from the lung.

In children with bronchiectasis open-air treatment, including open-air schools, is of great benefit. For the atelectatic type efforts should be made to re-expand the collapsed portion of lung by breathi exercises and CO_2 inhalations. When the collapse permanent, lobectomy may in the future become t best means of treatment. As the child gets old choice of occupation, avoiding dust-laden, close, over-heated atmospheres, is a matter of consideral importance.

Great Ormond-street.

SPECIAL ARTICLES

THE TREATMENT OF EARLY SYPHILIS

A REPORT OF AN EXPERT COMMITTEE OF THE LEAGUE OF NATIONS

THE Health Organisation of the League of Nations publishes[1] the results of an inquiry into syphilis treatment carried out in five countries (Denmark, France, Germany, Great Britain, United States of America); 93 clinics in these countries have contributed to the inquiry and 13,198 case-records of primary and secondary syphilis have been analysed.

Guided by the principles revealed by the study of these records, the experts who have collaborated[2] have adopted the following recommendations which are of great interest to syphilologists, public health officers, and private practitioners:—

1. Treatment should be recommended as early as possible in the sero-negative primary stage. In this connexion, the fullest possible use should be made, for purposes of diagnosis, of the microscopical examination of secretion from primary lesions, or from lymph glands.

2. It should be emphasised that, prior to the institution of either of the systems of treatment outlined below, there should be an adequate physical examination to determine the absence or otherwise of any indication for caution in respect of the dosage.

3. *It is essential that, in carrying out the treatment, a strict supervision of the patient be exercised, especially in respect of mucous membranes, skin, kidneys, and liver.*

4. Observation, clinical and serological, after completion of treatment should be adequate and in any case for not less than three years.

5. Adequate examination of the spinal fluid, at least before dismissal from observation, is essential.

6. The principles to be followed in carrying out the actual treatment should be as follows:—

(*a*) To employ a comparatively heavy individual dosage of the arsenobenzene and of the bismuth or mercurial compounds, the doses being administered in comparatively rapid succession, especially at the commencement.

(*b*) To maintain a persistent attack on the disease, avoiding intervals of such length as to afford the parasi an opportunity of recovering.

(*c*) To administer approximately as much treatment primary as to secondary cases.

7. The material studied does not enable a cle decision to be made as to the relative merits of inte mittent treatment, with courses of injections i rapid succession separated by rest intervals of som weeks, and continuous treatment, or between th simultaneous employment of both arsenical an bismuth or mercury and the system in which bismut and mercury are withheld until a number of arsenic injections have been administered.

Nevertheless it seems practicable from the resul of the analysis and from the personal experience of th experts to formulate a system of intermittent treat ment and *one of continuous treatment either of whic* can be expected to yield satisfactory results i ordinary cases of early syphilis.

It seems possible that the intermittent treatmen which is suggested below may in effect be continuous or *practically continuous, treatment owing to th* continued absorption of bismuth from the sites of th injection for some weeks *after any* temporar suspension of the treatment.

Plan of Intermittent Treatment

1. *Males.*—For adult males of average weigh aged less than 50 years and in whom there is no contra indication, a number of courses of injections on th plan described below (Table I.). It should be sai that, at the beginning of this course, some administe at once the full weekly dose (0·60 to 0·75 gramme) while *others divide it into two doses* (e.g., 0·30 an *0·45 g.) so far as the first week is concerned.*

TABLE I.—*Weekly Dosage*

Weeks.	"914" (gramme).	"606" (gramme).	Insoluble compound of bismuth containing bi-metal *; (gramme).
1st to 8th	0·60 to 0·75 or	0·4 to 0·5 and	0·20 to 0·24
9th	—	—	0·20 to 0·24
10th	—	—	0·20 to 0·24

* 1. By *insoluble* bismuth is here meant compounds of a ver slight solubility in water. They should therefore be given i suspension, those of extremely slight solubility (the oxychloride &c.) usually in a watery suspension, those that are more solubl (the subsalicylate, the iodo-bismuthate of quinine, the alkalin tartrates, &c.) suspended in a vegetable oil. If a *liposolubl* compound (e.g., t [illegible] &c.) is preferred, it i desirable that the [illegible] weekly in half doses *The dosage of* [illegible] should be calculated according to their content in bismuth metal.

[illegible] to bismuth, a course of mercury may be [illegible] rm of inunctions (40 days at 3 g. o [illegible] or of injections (70 mg. calomel o 120 mg. salicylate of mercury, &c., suspended in a suitabl base).

It is recommended that: (*a*) In cases which remain

or become serologically negative during, or by the end of, the first course four such courses be administered, with intervals of three to five weeks between any two courses.

(*b*) In cases which have not become sero-negative by the end of the first course, in addition to the amount of treatment shown in (*a*), further courses should be administered until the patient has received as a minimum three beyond that which has ended with negative serum reactions. At the option of the individual clinician, this treatment may be prolonged as may be considered necessary.

(*c*) Cases presenting signs of clinical relapse of an early type should be dealt with on principles similar to those enunciated in (*b*).

2. *Females.*—For females (non-pregnant), treatment should be administered on the plan outlined for men with the exception that the single dose of "914" should be reduced by 0·15 g. and that of "606" by 0·1 g.

In the event of any reduction in the amount of treatment being indicated it is recommended that this be effected by reducing the number of arsenical injections rather than by reducing the individual dose or increasing the intervals.

Plan of Continuous Treatment

The plan of continuous treatment is as shown in Table II. and the succeeding paragraphs.

As an optional scheme more in harmony with the trend toward longer courses, three series of ten to twelve injections each of the arsenical drug may be given. To secure an overlapping of the heavy metal and the arsenical, believed by some observers to protect against neuro-relapse, begin the bismuth two, three or even four injections before the end of the longer arsenical course, continue it through the period in which the arsenical is suspended, and on into the beginning of the next arsenical course. The bismuth is then suspended while the arsenical course is completed.

The bismuth salt advised for this system is bismuth salicylate in oil suspension, in full adult dosage, with due regard for weight. Other preparations of bismuth may be used only with due regard for their equivalent metallic content and for their rate of elimination. The mercurial inunction is [illegible] metallic mercury in a suitable base [illegible] per inunction, five or six inunctions per week [illegible] use of the iodide is optional, depending on [illegible]

The use of insoluble mercurials [illegible] in this system is not recommended.

It should be further noted [illegible] metal is employed after the [illegible] heavy metal courses are [illegible] intervals of six to eight weeks [illegible] of ten weeks injections, or [illegible] inunctions.

In cases of primary syphilis which have remained sero-negative throughout, a minimum of five courses of "606" or "914" should be given. Cases of sero-positive primary syphilis should receive the full treatment called for by this system.

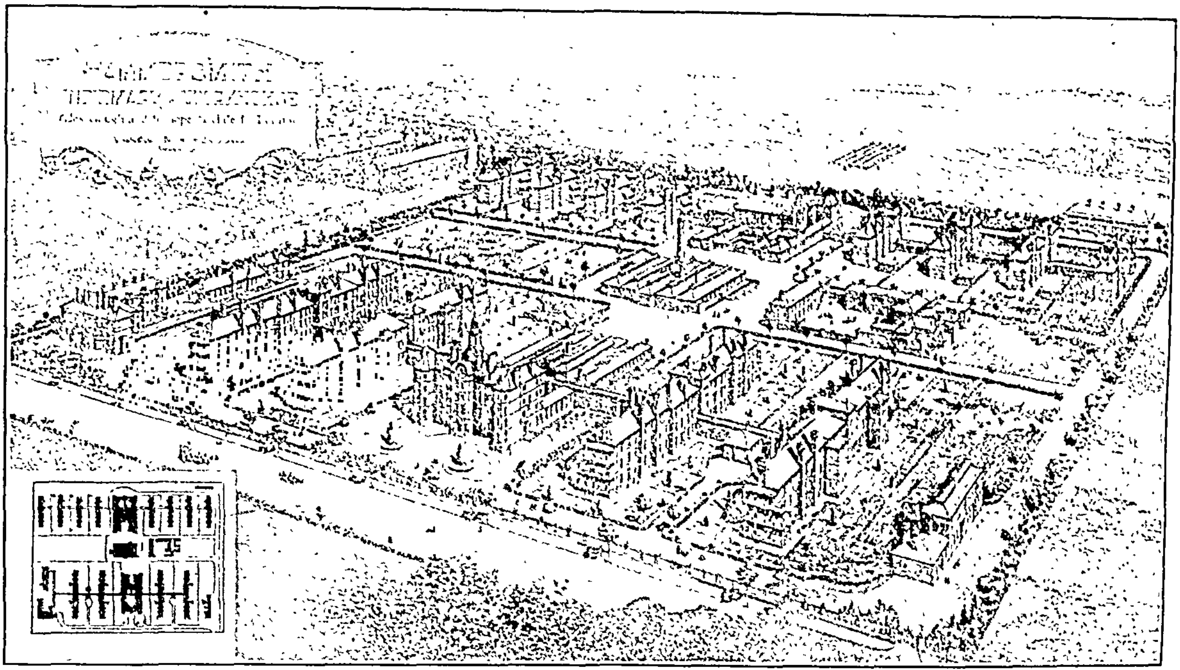

FIG. 1.—A bird's eye view of the Hammersmith Hospital as it was planned in 1905 by the architects, Messrs. Giles, Gough, and Trollope, but not then fully carried out from reasons of economy. The new out-patient department and the medical school building now make up the south-east block and complete the original scheme in this respect. The buildings of the institution to the north still afford great scope for future development.[*]

POST-GRADUATE MEDICAL TEACHING

PROGRAMME OF THE NEW HAMMERSMITH SCHOOL

THERE is something of adventure about the curriculum of the British Postgraduate Medical School opened by the King this week, for the staff has been taken from many parts of the Empire, the chairs of other Universities have been rifled, and the dean has been chosen from among distinguished administrative officers of the Indian Medical Service. The history of the school's development has already been told in these columns, with an account of the buildings themselves. What follows is intended simply to give an indication of the way in which post-graduate teaching is to take its course at present. Staff and equipment are there. Students have only been admitted officially since May 1st. They will be drawn from many sources, and it is hardly likely that the school will attain its greatest usefulness until arrangements are made for resident students. Many of the features suggested are still in the making; the most striking feature of the whole is the small provision made for the lecture type of teaching and the large provision for bringing students into personal contact with cases. In what follows we are much indebted to the dean and the heads of the four departments.

Department of Medicine

This department has charge of 170–180 beds distributed in six large wards. The full-time staff of the department consists of:—

Professor	4 First assistants
Reader	5 House physicians

and one assistant medical officer of the L.C.C. service who acts as resident medical officer. The first assistants are chosen for their expert knowledge of one or other of the various branches of medicine, such as neurology, respiratory and cardiovascular diseases, endocrinology, infections, in order that the specialised knowledge of the staff may cover a wide field. It is obvious that at any one time all the branches of medicine in which special knowledge is required cannot be represented on the staff, and to fill these gaps consultants have been appointed who visit the hospital at stated intervals, and at other times when their services are required. In the future it is hoped that additional departments, such as psychological medicine and diseases in childhood, may be added.

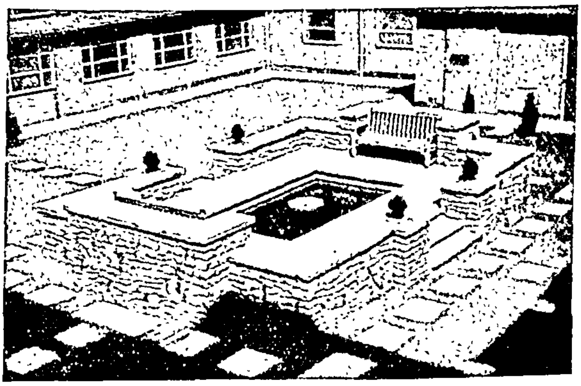

FIG. 2.—The fountain in the court of the school building which will no doubt become an informal consultation centre.

Each senior non-resident member of the staff, with a resident house physician, has charge of 25–30 beds. In addition to this duty each first assistant will give his expert special knowledge for the diagnosis and treatment of cases coming under his specialty throughout the wards of the department.

---

[*] With the exception of this photograph which we owe to the courtesy of the architects, all the other pictures in this article were specially taken for the purpose by Mr. C. M. Braithwaite, 103, Victoria-parade, Moseley, Birmingham, from whom prints of any of them can be obtained.

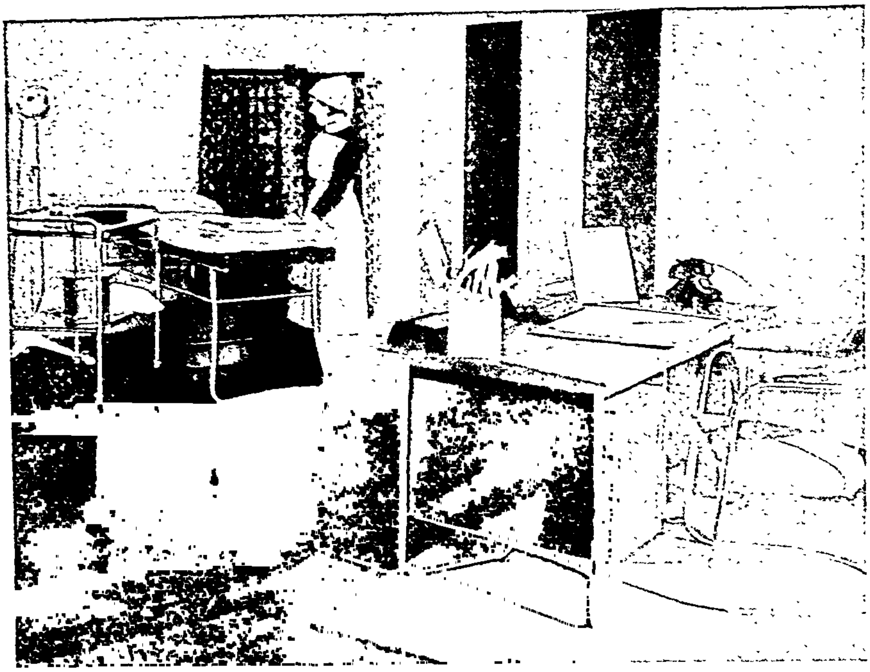

FIG. 4.—Physicians' examining room in the medical out-patient department. There are two large rooms as the one illustrated and two smaller rooms. The larger rooms are suitable for teaching. Entrance to the dressing rooms is seen behind.

In this way he will obtain material for his investigations and research and, at the same time, by means of the beds of which he is in charge and to which cases of all kinds are admitted, he will keep up his knowledge of general medicine. Each senior member of the staff will hold a consultative out-patient session on one morning a week, when he will see cases referred to him from the casualty department and patients discharged from the wards who require further treatment at the hospital or whose progress he desires to follow.

The house physicians and the officer loaned from the London County Council service are resident. The former will be recruited from the graduate students who have attended courses at the school. By allotting a comparatively small number of beds to each house physician opportunities are provided for them to study for higher degrees, prepare theses, attend other general or special hospitals, work in the laboratories, engage in research, and so forth. The house physicians are responsible for carrying out treatment and for the patients' records.

A small laboratory has been provided adjacent to each ward where simple laboratory tests can be carried out. Plans have been prepared for a series of laboratories for the physiological investigation of patients, including galvanometer rooms for work on the cardiovascular system, rooms for testing respiratory functions, basal metabolism, &c., and their construction is to be commenced immediately.

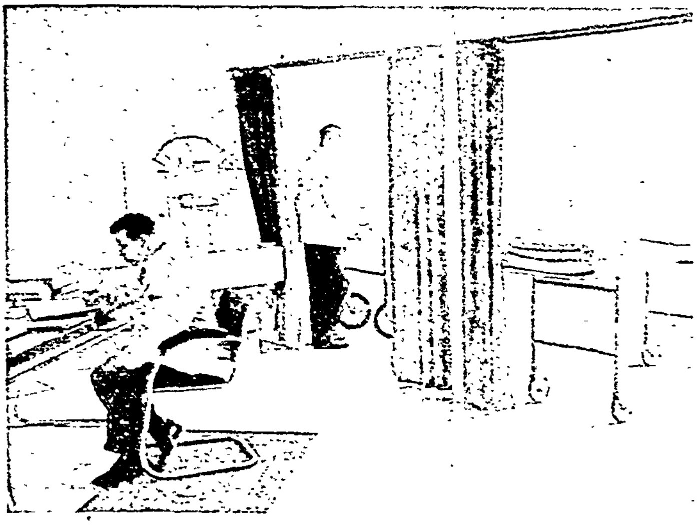

FIG. 3.—Receiving room in the new out-patient department. There are two such rooms, one for female patients and one for male. Patients are seen in these rooms at all times and may be dealt with immediately by the casualty medical officers, referred to the out-patient departments which are consultative, or admitted to the hospital.

COURSES OF INSTRUCTION

I.—Instruction in clinical medicine will be provided by appointments to the wards of graduate students in small numbers (about 15 students to 60 beds) for periods of three or more months. They will be allotted cases to which they will act as clinical clerks, recording fully the histories, physical findings and progress, aiding the house physician in carrying out treatment, and carrying out the simpler laboratory investigations that can be made in the ward laboratories. Bedside clinics or ward rounds will be held on two mornings (11.30 A.M.–1 P.M.) a week with the small group of students working in a ward, and on two mornings a week theatre clinics will be given by the professor or the reader for the whole number working in the department. On a fifth morning there will be a clinical-pathological conference at which all the students will attend, and on one afternoon a demonstration of X rays will be given by the lecturer in radiology. Post-mortem examinations are held daily, and demonstrations are given at 1.30 P.M. On most afternoons the students will be free to study their own cases, attend other general or special hospitals, or work for examinations. A good working library is provided.

II.—On three mornings a week out-patient sessions are held. These are consultative in character, cases being referred to them from the casualty department, and at them cases discharged from the wards and requiring further advice are seen also. Small numbers of students working in the wards assist at these sessions.

III.—Intensive courses for practitioners, lasting two weeks, will be given as frequently as practicable. In these courses a disease or group of diseases would be considered in a wide manner to illustrate the natural history of the process, the clinical manifestations, the physiology, pathology, and treatment. Clinical pathology, laboratory and X ray methods of diagnosis would be demonstrated. Subjects covered might include discussions—e.g., on (1) the place medicine and the doctor are taking in modern

A SPECIMEN WEEK OF INSTRUCTION IN CLINICAL MEDICINE

—	10–11.30.	11.30–1.	1.30–2.	2–3.	3–4.

society; the doctor's responsibilities to the State and to his individual patient; (2) methods of clinical examination and the importance of history taking; the study of the patient and medical psychology; (3) the physiology of the mind; (4) infections of the upper respiratory passages, acute and chronic; (5) chronic arthritis; (6) dyspepsia. In each case at least one outside member of the profession, expert in some branch of medical practice, would take part. This year it is proposed to hold such courses in June, July, September, and November; the number of practitioners attending will be limited to 25. The work will be as practical as possible and will include medicine, surgery, obstetrics, and pathology.

IV.—It is proposed to arrange a series of lectures and demonstrations on one afternoon or evening a week during the winter at a time suitable for practitioners in London. A series of subjects would be covered.

V.—Members of the medical profession, other than those on the whole-time staff of the school, will be invited to take part as teachers in the refresher courses and at the weekly lectures (III. and IV. as above). In this way the benefit of expert teachers in a large variety of subjects from London and elsewhere will be available for postgraduate instruction.

VI.—It is hoped that special lectures may be arranged to be given by distinguished visitors to London from

A SPECIMEN INTENSIVE COURSE FOR PRACTITIONERS

FIRST WEEK

—	10.30–1.0.	Conducted by—	2.0–4.30.	Conducted by—
Monday ..	Principles of the examination of patients.	Prof. Fraser and the medical staff of the school.	General principles in the treatment of Fractures.	Mr. Lambert Rogers and surgical staff.
Tuesday ..	At the Central London Throat, Nose, and Ear Hospital, Grays Inn-road.		At the London School of Dermatology, St. John's Hospital, Leicester-square.	
Wednesday ..	Natural history, diagnosis and treatment of Peptic Ulcer and various types of Functional Dyspepsias.	Dr. J. A. Ryle and the staff of the school, including the pathological and radiological staff.	Continuation of the same subject.	The same staff.
Thursday ..	Common types of Anæmia: their diagnosis and treatment.	Dr. Janet Vaughan and the staff of the school.	Demonstration of Obstetrical Cases.	Prof. Young and the staff of the school.
Friday	Antenatal Examination.	Prof. Young and staff.	Common Gynæcological Conditions.	Dr. Chassar Moir.
Saturday ..	Psychology in General Practice.	Dr. Edward Mapother.	—	—

SECOND WEEK

Monday ..	Gastric Carcinoma: its diagnosis and treatment.	Prof. Grey Turner and the staff of the school.	Heart Disease and Heart Failure.	Prof. Fraser and the medical staff of the school.
Tuesday ..	At Great Ormond-street Children's Hospital.		At Great Ormond-street Children's Hospital.	
Wednesday ..	Chronic Arthritis.	Dr. C. W. Buckley and the staff of the school.	Chronic Rheumatic Affections.	Dr. Buckley and the staff of the school.
Thursday ..	Some common Respiratory Diseases.	Dr. J. G. Scadding and the staff of the school.	Pulmonary Tuberculosis in General Practice.	Dr. L. S. T. Burrell and the staff of the school.
Friday	Head Injuries.	Mr. Lambert Rogers and the staff of the school.	The diagnosis of Acute Abdominal Conditions.	Prof. Grey Turner and the surgical staff of the school.
Saturday ..	Demonstration of Local Anæsthesia.	Dr. R. E. Apperly and the surgical staff of the school.	(12.30–1.30.) Discussion on the requirements of a Post-graduate Refresher Course.	Members of the class.

this country or from abroad as often as possible. In suitable instances the visitor will be invited to take charge of wards for a time and take part in the routine work of the hospital and school.

VII.—Graduates who are carrying out investigations and require clinical material for their researches can be accommodated in small numbers. It has not been possible as yet to provide laboratories for the department of medicine other than the ward side-rooms, but the plans for such laboratories have been prepared and their construction is to be commenced immediately. It will be possible to accommodate more research workers when these are completed.

VIII.—Graduate students attending for shorter periods than a month can be accepted in small numbers, but it may not be possible to arrange special courses of work for them. If they desire to study a special branch of medicine it may be possible to attach them to a member of the staff working in that special branch.

IX.—Visitors for short periods will always be welcomed, and arrangements will be made to enable them to attend and to see whatever aspect of the work of the department they desire.

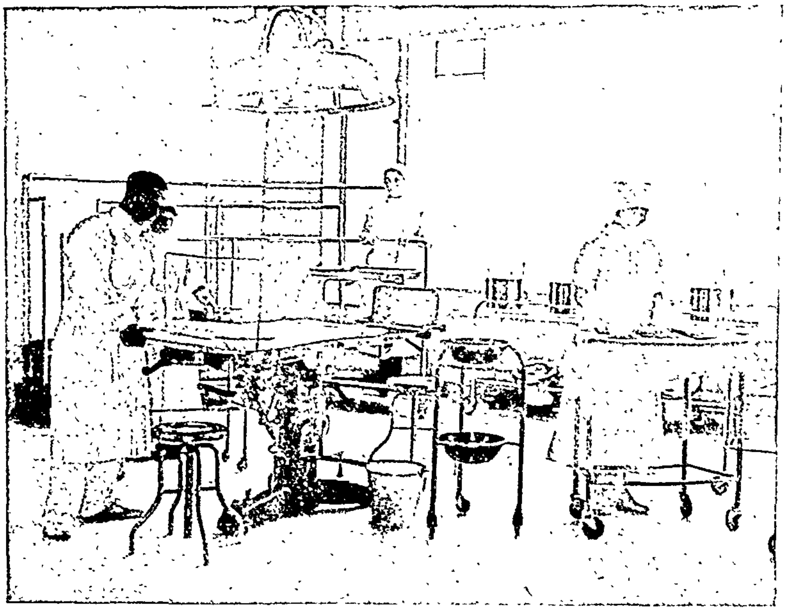

FIG. 6.—One of two new operating theatres on the top floor of the new hospital wing. In the background is seen a movable gallery for visitors. The sterilising room is common to the two theatres. The anæsthetic rooms adjoining can be darkened and used as adjuncts to the theatres for examinations or operations best conducted in *artificial light*. The surgeon's room is fitted for smaller demonstrations such as can be carried out between operations. A laboratory is provided in close proximity to the theatre.

Department of Surgery

Much of what has been said about the department of medicine applies in general to the department of surgery. At the moment the number of beds is rather less, 120 to 130, but next year it is intended to add another 50 in a new block of which plans have been approved. The staff is on the same basis as for the medical department though slightly fewer in number and consists of

Professor . . Reader . . 2 First Assistants . . 4 House Surgeons

and an experienced L.C.C. officer who acts as emergency surgeon and liaison officer. The members of the staff have all some special experience: the reader in neurological surgery, one assistant in urology, and the other in fracture work and orthopædics. The staff will thus include, beside the professor and the reader, three other members, one of whom will act in the capacity of resident surgeon, dealing with emergencies at such times as the visiting staff is not available. The other two members, of the standing of senior surgical registrars, will carry out and supervise special investigations, pre- and post-operative treatment and so forth. Each will have some special line in which his experience is valuable and which he will have the opportunity of developing. Four house surgeons have been appointed, their periods overlapping so that some would always be accustomed to the running of the unit. A considerable part of the teaching will be carried out in the demonstration theatre to which patients can be wheeled from ward and out-patient department. Ward visits, however convenient and delightful, are only suitable for demonstrating to a limited number and have the drawback that the remarks of the teacher have to be regulated to avoid hurting the feelings of the patient or other persons in the ward. Certain classes will also be held in the out-

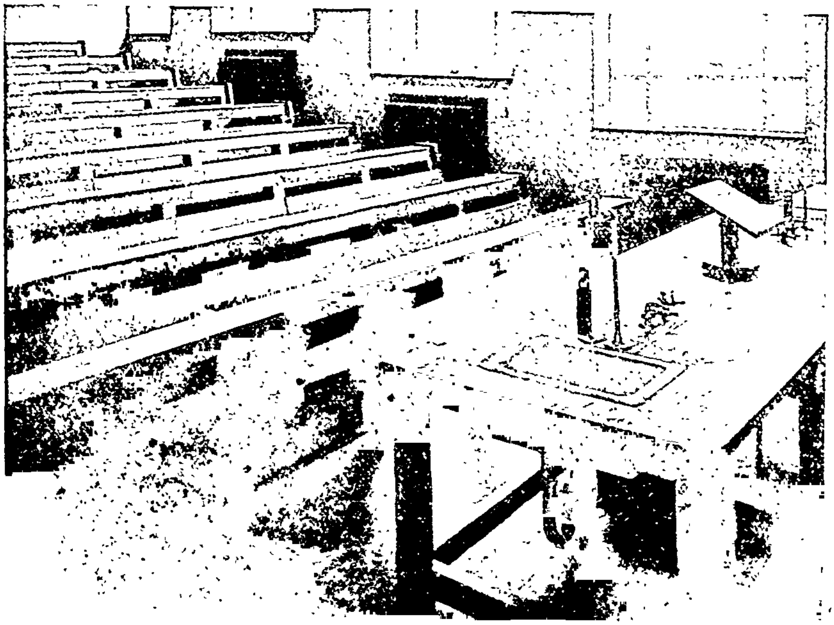

FIG. 5.—One of the two lecture theatres. The one on the ground floor, used as a clinical theatre, is fitted with projection lantern and cinematographic apparatus. Each of the theatres can accommodate about 100 students.

It will thus take a part, though probably a minor one, in "refresher" courses and participate to some extent in other activities of a similar nature. The special object of the department will be to provide medical men and women with facilities for advanced study in all branches of pathology. Such students will be of two main types :—

(A) Those who desire to gain general training and experience in one or more branches of the subject.

(B) Those who wish to devote themselves to the investigation of some particular problem.

The department will in fact be concerned with students of pathology rather than with students of medicine to whom pathology is but one of several subjects engaging their attention.

In order to meet the needs of such students, especially those in Group A, the department must have access to teaching material. This can only be obtained from the routine pathological services of the hospital, and the department will therefore be responsible for these services. Such an arrangement has the advantage of ensuring that close association between the clinical and the laboratory sides which is so desirable. While chiefly concerned with the problems of the student of pathology, an important function of the department will be to collaborate with members of the clinical departments in combined investigations and to provide facilities and assistance to members of the staffs of these departments who may wish to undertake personal laboratory work. The successful development of a department of this kind demands that every member of its staff shall be actively engaged in research, for an institute which will attract serious students of pathology who wish to undertake original investigations, and to be trained in the methods of research, can only be built up if the staff are themselves students and not merely teachers. For this reason care has been taken to provide a staff sufficiently large to ensure that each individual may have adequate time, apart from his routine duties, to devote to his personal work. The organisation of the department provides for readerships in morbid anatomy and histology, bacteriology, and pathological chemistry; and each reader will have at least one assistant. Students can be admitted into any one of these three subdepartments, or divide their time among two or all of them. There is, in addition, a subdepartment of clinical pathology where candidates for the University diploma in clinical pathology will find their requirements met.

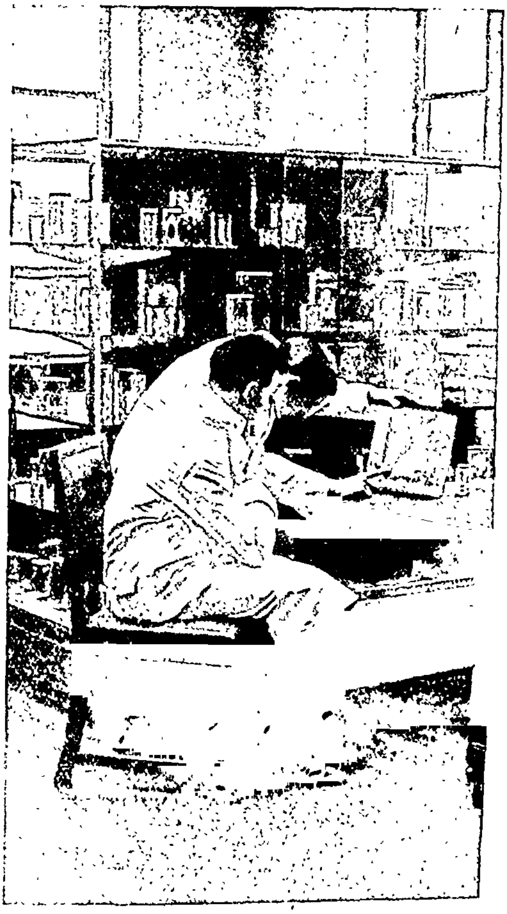

FIG. 11.—A corner of the museum on the first floor. The available space is limited and the museum will be strictly a teaching one.

Instruction in pathology at the Hammersmith school will be of a very personal character. Students will work in the laboratories under direction of members of the staff carrying out the ordinary pathological investigations for the hospital, and research students will be mainly occupied with their individual problems. Formal teaching will play little part in the scheme, but pathological conferences open to anyone who desires to attend will be held on one or two afternoons a week when the routine work of the department will be discussed by the staff and the students. Post-mortem demonstrations are now being held every day when opportunity

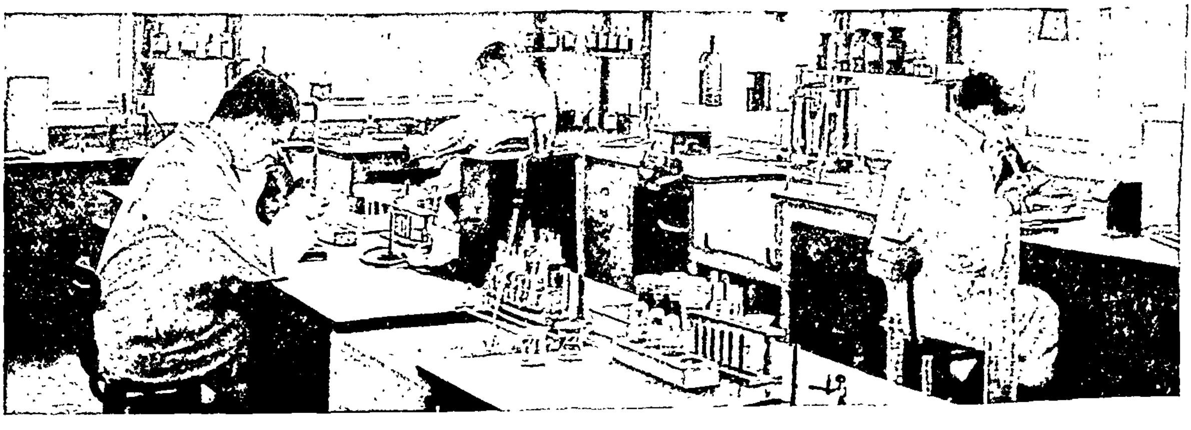

FIG. 10.—A histological laboratory adjoining the post-mortem room.

offers at 1.30 P.M. These are open to everyone, and the professor of pathology will combine with the professor of medicine in a clinical pathological conference once a week. One of the other weekly conferences will be devoted to the post-mortems of the week in which cases will be dealt with from a more pathological point of view, and students will be able to enter more deeply into the bacteriology, chemical pathology, and biochemistry of the material.

It will now be obvious that pathology at the Hammersmith school is not to be regarded as a separate *Fach* or discipline but as a habit of mind pervading every aspect of medical inquiry.

List of the Professorial Staff of the School

Dean: Col. A. H. Proctor, D.S.O., I.M.S.

MEDICINE

Professor	F. R. Fraser, M.D. Edin., F.R.C.P. Lond.

Pediatrics	Dr. Alan Moncrieff.
Ophthalmology ..	Mr. R. C. Davenport.
Ear, Nose, and Throat	Mr. Sydney Scott.
Neurology	Dr. J. Purdon Martin.

MEDICINE AND THE LAW

Capacity of Injured Workman

In Cunard Steamship Co. *v.* Moore the House of Lords not long ago refused to allow the Court of Appeal to overrule a county court judge on a point of medical evidence. It was a case of workmen's compensation. Moore, working on a ship, had his left arm caught in the rope of a derrick. Both bones of the left forearm and also two ribs on the left side were fractured. He was paid full compensation at the agreed rate of £1 6*s.* 4*d.* per week from the end of 1930 to Feb. 9th, 1933. Dr. X then certified that Moore had so far recovered as to be able to perform heavy work; his wrist movement would improve by doing work. Accordingly the employers gave notice under Section 12 of the Act and diminished the weekly payment to 10*s.* Moore asked for light work for five and a half days a week at an ordinary dock labourer's pay. This was refused. Subsequently he asked for arbitration, claiming compensation on the basis of total incapacity as from Feb. 25th, 1933. The Steamship Co. answered that in the month of February Moore was only partially incapacitated and had since entirely or almost entirely recovered. At the arbitration in the Liverpool county court Dr. Y, giving evidence on behalf of Moore, said the man could not do full work and no improvement was to be expected. Dr. X testified on the other hand that Moore's injuries would cause him discomfort but not incapacity for dock labour; he could now do full work and would improve and be all right in six months. The county court judge, accepting the evidence of Dr. X, found that Moore was, at the date of the hearing, fit for full work and that his incapacity had ceased. On appeal the Court of Appeal held that the evidence in the county court had shown that the capacity for work was not that of an ordinary healthy man and that there was no evidence that the incapacity had ceased. The Court of Appeal sent the case back to the county court for assessment of the amount of compensation payable. In January, 1934, an award of 10*s.* a week was made, to begin at June 16th, 1933, and to continue during the partial incapacity. The Cunard Co. accepted this award for four months and paid compensation thereunder; it then appealed to the House of Lords, where the order of the Court of Appeal was discharged and the county court judge's decision was restored. Lord Blanesburgh said that the true effect of the evidence given by Dr. X (that the incapacity had now ceased) was something which could be better appreciated by the county court judge who heard the evidence personally than by the appellate courts which did not hear it. There was evidence on which the county court judge could find that incapacity "from every relevant point of view" had ceased. It was of the first importance, said Lord Blanesburgh, that the finality of an arbitrator's findings of fact in workmen's compensation cases should be jealously maintained.

Handwriting Experts

Of all species of expert witnesses the handwriting experts seem to be the most vulnerable. Defending advocates never spare an allusion to the Beck case and now the Binney case adds another arrow to their quiver. Binney was indicted at the Derbyshire assizes last July for having sent letters to a Mrs. Clift demanding money with menaces. Although the charge accused him of having "uttered" the letters and not of having written them himself, the prosecution ran its case on the basis that the handwriting was that of Binney. Convicted in July, he asked on August 15th for leave to appeal. There was no fresh evidence as a ground for disturbing the jury's verdict, and the Court of Criminal Appeal dismissed his application. On August 28th another letter of the same character reached Mrs. Clift. Binney then petitioned the Home Secretary. On March 5th and April 3rd two more such letters arrived and a few days ago, on the eve of the reconsideration of the case by the Court of Criminal Appeal at the instance of the Home Office, a fourth letter came. At the recent hearing there was expert evidence (apparently not disputed by the Crown) that these four post-conviction letters were written by the same hand as the letters on which Binney had been found guilty. An officer from Dartmoor Prison, where Binney was serving his sentence, said that was no record of anyone having visited the man in prison; there was further evidence that the letters could not have been sent from the prison. It was of course possible that Binney had written the four letters before his trial to be posted at intervals later; but the post-conviction letters dealt with events which happened while he was in prison and one letter actually named the precise term of sentence he had received. It was possible too that a confederate was working with him and was managing the post-conviction correspondence; but the jury at the assizes had convicted Binney on the basis of his having been the sole person concerned. "It is clearly established," said Lord Hewart, in delivering the judgment which has now set Binney at liberty, "from materials which were not open to any court in July, that there is a hand somewhere, other than the hand of Binney, which is responsible for the physical act of writing these letters." The court was obliged to conclude that, if the jurors had had these fresh materials before them, they would not have come to the conclusion that he was guilty of the charge.

The difficulty of the handwriting expert is that he has often to bear a disproportionate burden in supporting a case where other kinds of evidence are missing. It is for the jury to say what weight is to be attached to what he says. A jury can see similarities of script or spelling readily enough, but it is convenient that someone should point them out first. Sometimes the handwriting expert can make an overwhelming case with decisive effect. This happened on the prosecution of Bruno Hauptmann, the alleged kidnapper of the Lindbergh baby. A letter demanding a ransom was left in the child's nursery on the night of the crime; other letters were written in the course of extracting the 50,000 dollars which Colonel Lindbergh paid in vain; one letter concerned the production of a "token" of authenticity, namely, the garment which the child had been wearing. There were 14 of these "ransom notes" and 16 acknowledged specimens of Hauptmann's actual writing, such as his application for a motoring licence and certain specimens written by him at the dictation of the police. Particular letters, such as an uncrossed "t," and a peculiar "x" which resembled a double "e," were common to all the writings. Spelling mistakes made another connecting link—"note" for "not," "gut" for "good," "mony" for "money," "boad" for "boat," "hte" for "the," and so on. Another was the idiosyncrasy of hyphenating "New-York." All these points a jury could easily follow, and their cumulative effect would be strong. These and other matters (such as the tracing of the ransom money and the identification of wood in the kidnapper's ladder with wood taken from Hauptmann's house) are admirably presented in a recent account of the case (The Lindbergh Crime, by Sidney B. Whipple, 6*s.* net, Methuen). It is a thrilling story.

A Problem of Professional Secrecy

There is no end to the problems which can arise or can be invented in respect of professional etiquette. Life, unhappily, is not so simple that the questions can always be answered with an absolute "Yes" or "No." Here is a conundrum about the duty of secrecy. A doctor attends a woman of about 75 in excellent health. The patient has a son with expectations under his mother's marriage settlement. He stands to receive a certain sum from the estate and is anxious to raise money on his prospects. Naturally the amount of the advance which he can obtain from an insurance company or other lender will depend on the probable duration of his mother's life. His solicitor, who is arranging the transaction, asks the doctor to express an opinion how long the lady is likely to live. Is the doctor betraying professional confidence if he does so?

The first reflections that suggest themselves are mainly negative. If the patient herself gave the doctor permission to answer the solicitor's question, all would be well; but presumably the matter is too delicate for the son to mention to his mother, though this is the proper way to regularise matters. The son has every right to arrange the advance in his own interests but he is not his mother's agent in so doing; consequently, as a matter of strict technicality, he has no authority to put the question to his mother's doctor for his own commercial purposes—still less has the solicitor. Certainly it would seem improper for the doctor to furnish the solicitor with a formal opinion about the patient for a fee without the patient's consent; if there is doubt whether the doctor should divulge information, he had better not sell it. Yet in spite of the rigid rules of non-disclosure and the practitioner's instinctive desire to keep on the right side in a case of doubt, there are two other considerations which may seem to permit a reasonable latitude. First, there is never the same degree of secrecy where relatives or members of the same household are concerned. A father will obtain frank information from the doctor who examines his child; he is legally and morally responsible for his children's health. By analogy a mistress who calls in a doctor to attend a domestic servant will be told whatever is necessary in the interests of the patient's treatment. And family ties of affection and sympathy make it natural that a medical practitioner should be willing to discuss the health of a patient with other members of the patient's household. Nor is the commercial element entirely irrelevant. There may be a question of economy in the matter of terminating a servant's contract of service for illness or of sending a member of the household to hospital. In the case of the son in the problem, if he asked the question

"Well, doctor, how long do you think my mother is likely to live ?" it is unlikely that the doctor would feel obliged by an iron-bound sense of etiquette to refuse a reply, though the reply might not be sufficiently formal for the purpose of the son's transactions with the solicitor. Secondly, it is to be remembered that the patient in our problem enjoys good health. There is thus the less to divulge. Certain legal cases and judicial dicta have indicated that the patient may have a right to sue a too loquacious doctor for damages. But neither as a matter of law nor as a matter of etiquette has a doctor done much harm if he replies "your mother enjoys excellent health and I know no reason why she should not be spared to you for many years yet." As a matter of commerce, of course, the answer is little help to anyone who wants to raise money on expectations maturing at the patient's death. Terms based on the normal expectation of life can hardly be improved for the reversioner unless the report of the patient's health is unfavourable.

These casuistical questions as to what Dr. A should do in a particular situation invite diffuse speculation. Such situations doubtless occur in real life and somehow Dr. A manages to meet them without sensational consequences.

PUBLIC HEALTH

Economic Depressions: 1862 and 1935

THE recent issue by the Ministry of Health of a report[1] on conditions in an area subject to prolonged unemployment makes it opportune to recall the last detailed medical report on such a subject, that presented by Dr. (later Sir George) Buchanan at the time of the distress in the cotton trade consequent upon the American Civil War.[2]

Arnold's "History of the Cotton Famine" passes under review the period from April, 1861, to July, 1863, and indicates its peak as occurring in 1862, in the early months of which year "gaunt distress was advancing with rapid strides." The general use of the term "cotton famine" is itself ominous, though the historian is careful to dissociate it from the extreme meaning of the similar term as applied to the potato famine of Ireland: "but no such sorrow, no such shame as this, lies at the door of the wealthiest of the English counties. Suffering there was, sad and enduring, but not such as this."

The distress struck suddenly a wide community unprovided with social services as we understand them to-day, and there were no resources save the rapid expansion of poor-law relief and public charity. The extent of the calamity and the measures of relief are set out in Arnold's History and in Dr. Buchanan's report. When Dr. Buchanan wrote, in December, 1862, it was estimated that of half a million cotton workers half were wholly unemployed, a third were working short-time, and only a sixth were in full work. It was further estimated that another half a million people were directly dependent upon the cotton operatives and so involved in the calamity. The scale of relief which was adopted varied as between different boards of guardians but at the time of the report the average income from all sources was taken as nearly 2*s.* per head per week, exclusive of clothing, bedding, and firing which might be supplied in addition. There was, however, a sliding scale of relief according to the number in family and on the 2*s.* basis this is indicated as being for one person 3*s.* 4*d.*, man and wife 6*s.*, man, wife, and one child 7*s.*, with an additional allowance of 1*s.* for each child, so that with six children the family relief was 12*s.*, considerably less than 2*s.* per head. It was further estimated that in a household of four the amount available for food was 1*s.* 5*d.* per head per week. The Manchester retail prices of certain articles of food are quoted in the report on a quantity regarded as the average a single person would be likely to purchase for a week's consumption. If we compare these prices with those given as the B.M.A. mean in Appendix C of the report of the Committee on Nutrition we have the following figures:—

	1862. *s.*	 *d.*	1933. *s.*	 *d.*
Bread, 8 lb.	1	0	1	2
Potatoes, 5 lb.		3		3·7
Oatmeal, 2 lb.		4		5
Tea, 1 oz.		3		0·8
Sugar, ½ lb.		2·5		1·125
Bacon, ¼ lb.		1·75		1·5
	2	2·25*d.*	2	2·125*d.*

The fall in the price of tea and sugar, important articles of consumption, is noticeable. On the other hand, rent was a much smaller item, the figure quoted being 1*s.* per week. When due allowance is made for variations in the value of money, it is obvious that the financial provision was on a lower scale than prevails to-day.

What was the reaction on health to these conditions ? Dr. Buchanan's report is based on his own observations and those of thirty medical practitioners holding public appointments. There does not appear to have been any general increase in mortality: the average number of deaths from all causes for the years 1857–61 in the twelve unions visited is given as 8353, while the figure in 1862 was 7427. An examination of the Registrar-General's tables shows the annual rate of mortality per cent. in Lancashire over the years 1854 to 1863 to have been 2·701, 2·680, 2·464, 2·628, 2·719, 2·454, 2·371, 2·592, 2·560, 2·629. This aspect of the situation is dealt with at some length in Arnold's "History" where emphasis is laid on the lesser consumption of alcohol and the increased care of children due to the enforced attendance at home of their mothers. The following quotation is illustrative:

> It was well said by the sexton of one of the most important towns in Lancashire, when asked how it happened that his lugubrious trade was unusually inactive during the summer of this year, "Well, thae sees," he answered, "poverty seldom dees. There's far more kilt wi' o'er-heytin' an' o'er-drinkin' nor there is wi' bein' pinched,"—a truth which contains a moral lesson valuable to all classes.

This absence of an increased total death-rate is, however, countered by increased manifestations of morbidity in various directions which are considered by Dr. Buchanan under several headings of causation. He refers to loss of strength, colour, and flesh among the *cotton-workers as a body*; to the observations made that "the parents have lost their health much more generally than the children, and particularly that the mothers, who most of all starve themselves, have got pale and emaciated"; to a generally asthenic type of disease; to a hæmorrhagic tendency; to a high prevalence of bronchitis and pneumonia; to an unparalleled quantity of itch; to grave complications of measles and scarlatina; and to an outbreak of typhus in a severe form, in which the death-rate at Preston was 23 per cent. The conclusions of the report are as follows:—

---

[1] Report of an Inquiry into the Effects of Existing Economic Circumstances on the Health of the Community in the County Borough of Sunderland and Certain Districts of County Durham. Cmd. 4886. See THE LANCET, May 4th, 1935, p. 1058.

[2] Dr. Buchanan's report (Dec. 30th, 1862) on the Health of the Operatives as affected by the Prevailing Distress. Fifth Rep. Med. Officer of the Privy Council, 1862, Appendix V.

> 1. That while actual death from starvation has been of the rarest occurrence, there is a peculiarly low state of health among the unemployed operatives of the cotton towns, showing itself particularly in the elder people, and predisposing to various diseases.
>
> 2. That scurvy and other evidences of a tendency to hæmorrhage have been seen with remarkable frequency.
>
> 3. That lung diseases of a sort to be induced and aggravated by exposure have been rife, even out of proportion to the cold of the season.
>
> 4. That epidemic measles and scarlatina have habitually exhibited peculiarities that in ordinary times are only met with in weakly constitutions. That true typhus fever has shown itself. That epidemic diarrhœa has been below the average, except in Preston, which is the town that has suffered most from typhus fever.
>
> 5. That disease from drunkenness and from neglect of children has been less common than in ordinary times.

The report recently issued by the Ministry of Health on the existing conditions in Sunderland and certain districts of Durham was reviewed in our columns on May 4th. It refers to a period of more prolonged distress, countered by more advanced measures of public health.

Pasteurising Plants

The consumption of pasteurised milk is rapidly extending and it becomes ever more important that the milk should be pasteurised properly so that the term "pasteurised milk" should really connote safety. For this reason Sir Weldon Dalrymple-Champneys was invited by the Ministry of Health to prepare a report on the supervision of milk pasteurising plants which has just been issued.[1] Sir Weldon has no doubt that pasteurisation carried out in such a way as to meet the requirements of the Milk (Special Designations) Order of 1923 renders milk safe. Milk can, however, be recontaminated with pathogenic organisms after pasteurisation and, unless the milk is heated so long as to impair its physical qualities, some spore-bearing organisms are apt to survive. For this reason pasteurised milk will ultimately go sour. But even efficient pasteurisation need not interfere with the preservation of the cream line which is so important a commercial requirement, for the depth of cream separating out on the top of the milk on standing is regarded by many sections of the public as an indication of quality. Sir Weldon says he has seen many pasteurised milks properly pasteurised in efficient plants which showed a cream line at least as good as the majority of raw milks. Failure to secure efficient pasteurisation arises chiefly from lack of knowledge how to construct, install, and use efficient apparatus, and the report is an endeavour to give in concise form the information needed by officers of a local authority for the efficient discharge of their duties in connexion with licensing and supervising such plants. Sections on bottle filling and bottle washing have been added, for inefficiency at these stages is a common cause of failure to attain the bacteriological standard for pasteurised milk laid down in the Order.

Grit and Fumes in London Air

The London County Council is a jealous custodian of the amenities of the metropolis and no respecter of persons when these amenities are imperilled. The furnaces of the Stepney generating station in Limehouse have for 15 years past emitted smoke and grit of which the inhabitants have complained. An injunction was obtained against the borough council in June, 1920, and upheld on appeal when the court ruled that the nuisance was a real one, even taking into consideration the character of the neighbourhood. Two years ago complaints were again made and the L.C.C. chemist reported that one chimney-stack was discharging in 24 hours nearly 4 cwt. of grit containing 28 per cent. of unburnt matter. The Electricity Commissioners who were then consulted suggested the erection of a new chimney and the installation of dust extraction plant, measures which could be completed within 12 months. Although the twelvemonth is up it seems that nothing has been done to implement these measures, and temporary remedies have proved inadequate. The L.C.C. is now to press the Minister of Health for leave to take action against the Stepney council.

At the new Battersea power station the plant for eliminating sulphur fumes, smoke, and grit has fulfilled the expectation raised in the experimental stage, but in view of the second half of the station still to be erected the L.C.C. is unwilling to take any risk because the problem is a new one and a further improvement in the processes may reasonably be anticipated. The L.C.C. would like to see a Government committee set up to undertake research into the general question of the best means of removing sulphur compounds from flue gases. Representations to this effect are to be made to the Ministers of Transport and of Health.

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDED MAY 4TH, 1935

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 0; scarlet fever, 1905; diphtheria, 915; enteric fever, 11; acute pneumonia (primary or influenzal), 1182; puerperal fever, 47; puerperal pyrexia, 114; cerebro-spinal fever, 22; acute poliomyelitis, 3; acute polio-encephalitis, 1; encephalitis lethargica, 10; dysentery, 13; ophthalmia neonatorum, 103. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the London County Council on May 10th was 3403, which included: Scarlet fever, 1040; diphtheria, 1368; measles, 29; whooping-[illegible] fever, 27 mothers (plus 7 babies); [illegible]; poliomyelitis, 3. At St. Margaret's [illegible]ies (plus 9 mothers) with ophthalmia neonatorum.

Deaths.—In 121 great towns, including London, there was no death from small-pox, 1 (1) from enteric fever, 31 (0) from measles, 7 (2) from scarlet fever, 33 (4) from whooping-cough, 39 (7) from diphtheria, 51 (16) from diarrhœa and enteritis under two years, and 125 (16) from influenza. The figures in parentheses are those for London itself.

Influenza is on the wane, but Liverpool reported 14 deaths, Manchester 9, Middlesbrough 7, Newcastle-on-Tyne 6, Salford 4, no other great town more than 3. Five fatal cases of measles were reported from Liverpool and from Wigan, 4 from Cardiff. Preston had 4 deaths from diphtheria.

The number of stillbirths notified during the week was 273 (corresponding to a rate of 36 per 1000 total births), including 40 in London.

PANEL AND CONTRACT PRACTICE

Employment of Assistants

THE medical benefit regulations lay it down that an insurance practitioner may not have included in his list more than 2500 insured persons (in some areas the maximum is determined by the local insurance committee at a lower figure) unless he is working in partnership, in which case any member of the partnership may accept up to a maximum of 3000 provided the average for the partnership does not exceed 2500. If an assistant is employed with the consent of the insurance committee the principal may accept further insured persons up to a maximum of 1500. Insurance committees in consenting to the employment of an assistant usually stipulate that the assistant shall have his name included in the Medical List, and while this is a useful precaution it sometimes leads to misunderstanding inasmuch as there is no obvious provision to prevent an assistant accepting insured persons in his own name. For various reasons, however, it is undesirable that he should do so, particularly as in many cases the assistant is merely waiting until he can secure a practice of his own—it is no longer correct to describe him as waiting for his beard to grow. Assistants consequently change quite often, and apart from the undesirability of frequent changes of doctor requiring to be notified to the patients, it is fundamental that the principal should be the responsible practitioner in relation to all the patients associated with the practice.

The regulations are silent as to the definition of an assistant, but clearly it is necessary that both practitioners and committees should have a definite understanding of what constitutes an assistant, especially when the assistant is engaged in order that the principal may exceed the normal limit of acceptances. Other things being equal it is a mathematical certainty that the practitioner with (say) 2550 insured persons will require less help than his neighbour with 3800. What then does satisfy the requirement to employ an assistant? In London the committee require that the principal shall have at all times the first call on the services of the assistant even if he is not employed full time. A practitioner with patients of his own cannot fulfil this condition, as his responsibility for his own patients must form the first call on his services.

In some areas there is a clause in the distribution scheme which provides that even if a practitioner's list temporarily exceeds the permitted maximum he shall not be paid in respect of the surplus, and as a logical outcome of this provision it is necessary to ascertain quarter by quarter that practitioners, who, owing to their having been given consent to employ an assistant, have an additional number of patients, have actually continued to employ their assistants. At a recent meeting of the London insurance committee it was reported that two practitioners with slightly over the permitted maximum for a practitioner working single-handed had been without assistants, in one case for a complete quarter, and in the other for about five weeks. In the former case the termination of the arrangement was deliberate and the remuneration of the practitioner was reduced accordingly, but in the other efforts to obtain a new assistant had been made without success, and in view of this fact and of the provision in Clause 6 (5) of the allocation scheme that a practitioner whose list is found to be in excess has a period of two months from the date on which the excess was discovered within which to take a partner or assistant, or to reduce his list to the appropriate figure, the committee decided that for the quarter in question payment should be made in accordance with the number of insured persons on the practitioner's list.

Prescribing

During 1934 prescriptions for insulin to the number of 31,357 were dispensed for insured persons in London at a total cost of £9392 16*s.* 11*d.*

Modern conditions of life are sometimes accused of causing digestive troubles. During the month of January 11,706 prescriptions for 40,904 apothecaries' ounces of non-proprietary compound bismuth powders were issued in London. The ingredient cost of a ton and a quarter of this preparation was £264 11*s.* 8*d.* Only eight prescriptions for proprietary brands were issued during the same period.

OBITUARY

SIR THOMAS STAFFORD, Bt., P.C., F.R.C.S.I.

LATE MEDICAL COMMISSIONER, LOCAL GOVERNMENT BOARD, IRELAND

THE death occurred on Saturday last, May 11th, of Sir Thomas Stafford, a prominent worker in the cause of public health in Ireland. Born in 1857, son of John Stafford of Portobello, a well-known Roscommon family, he received his medical training in Dublin and qualified in 1882 with the double diploma of the Irish Colleges. He entered practice in his native county as dispensary doctor at Boyle, but shortly afterwards obtained the position of medical inspector to the Local Government Board of Ireland. He took the D.P.H. of the Irish Colleges in 1898 and was admitted F.R.C.S.I. in 1899, having already been appointed a medical member of the board, a position which he held for many years. He became prominent in the great health campaign inaugurated by Lady Aberdeen, and his services when he became a medical commissioner of the board were conspicuous in the cause of public health. A courteous, sympathetic, and particularly able administrator, he gave every encouragement in his power to all movements for the improvement of the public health of the country, and of the professional status of the medical man in the poor-law service. In 1906 he was appointed C.B., in 1913 was created a baronet, and shortly after became a member of the Irish Privy Council. He was a D.L. for Co. Roscommon.

On his retirement from his official duties, Sir Thomas Stafford became a great supporter of outdoor sport, fishing, shooting, and especially racing, in connexion with which he was for a time a steward of the Irish Turf Club. His death occurred at Lord Headfort's house in Kells; he had been in bad health for some time previously. He married in 1890 Frances, only child of the late Colonel E. R. King-Harman; she predeceased him and his son Captain Cecil Stafford King-Harman succeeds to the baronetcy.

THE SERVICES

ROYAL NAVAL MEDICAL SERVICE

Surg. Rear-Admiral P. Pick to *Pembroke* for R.N. Hosp., Chatham, and as Medical Officer in Charge.

Surg. Rear-Admiral W. W. Keir, C.M.G., has retired at his own request on relinquishing the command of the R.N. Hospital at Haslar.

Surg. Rear-Admiral Keir was the senior officer of his rank on the active list and entered the Navy on Nov. 8th, 1898, and served with distinction in the war. In 1928–30 he was in charge of the naval hospital at Hong-Kong. Consequent on the vacancy thus occurring, Surg. Capt. F. J. Gowans, senior medical officer in the hospital-ship *Maine*, has been promoted to Surg. Rear-Admiral. He joined the Navy in November, 1903, and served as staff surgeon in the *Queen Mary*, *Challenger*, and *Albion*. From 1928 he was surgical specialist at Haslar Hospital and became Surg. Capt. in December, 1929.

Surg. Capt. F. J. Gowans, M.B., to rank of Surg. Rear-Admiral.

Surg. Comdrs. W. H. Murray to *President* for course; and M. B. Devane to *Keith*.

Surg. Lt.-Comdr. (D) T. E. Brevetér to *Victory* for R.M. Infirmary, Eastney.

Surg. Lt.-Comdr. D. C. Drake to *Drake* for Plymouth Hospital.

Surg. Lt. D. G. Yendoll to *Pembroke* for R.N.B.

Surg. Lt. W. S. Davidson, short service engagement terminated.

ROYAL NAVAL VOLUNTEER RESERVE

Surg. Comdr. W. F. W. Betenson to *St. Vincent*.

Surg. Lt. H. L. Hoffman promoted to Surg. Lt.-Comdr.

Surg. Lts. J. N. Matthews to *Nelson;* C. Seeley to *Curacoa;* and G. H. Sellers to *Tiverton.*

Proby. Surg. Sub.-Lt. P. H. K. Gray to *Rodney.*

ROYAL ARMY MEDICAL CORPS

Short Serv. Commissions.—B. d'Epinay Barclay to be Lt. (on prob.).

REGULAR ARMY RESERVE OF OFFICERS

Lt.-Col. P. Dwyer, M.C., having attained the age limit of liability to recall, ceases to belong to the Res. of Off.

TERRITORIAL ARMY

Lt. E. F. S. Morrison to be Capt.

K. G. W. Saunders (late Offr. Cadet, Univ. of Lond. Contgt. (Med. Unit), Sen. Div., O.T.C.) to be Lt.

G. O. Gauld (late Offr. Cadet, Cambridge Univ. Contgt., Sen. Div., O.T.C.) to be Lt.

R. D. Forsyth (late Offr. Cadet, Glasgow Univ. Contgt., Sen. Div., O.T.C.), to be Lt.

ROYAL AIR FORCE

Flight Lt. J. S. Carslaw is granted a permanent commission in this rank.

Flight Lt. O. S. M. Williams to Air Armament School, Eastchurch.

INDIAN MEDICAL SERVICE

The undermentioned appts. have been made:—

A.D.M.S.—Col. R. E. U. Newman, O.B.E., M.C., M.B., Brit. Serv.

D.A.D.P.—Capt. A. T. H. Marsden, M.D., R.A.M.C.

Majs. to be Lt.-Cols.—A. H. Shaikh, R. M. Kharegat, and J. C. Pyper, O.B.E.

The appts. of the undermentioned officers are confirmed:—

Lts. (now Capts.).—B. F. B. Russell, R. L. H. Minchin, W. G. Kingston, J. Edis-Myers, R. de Soldenhoff, C. J. Hassett, R. R. Prosser, E. Parry, W. G. Kennedy, and P. I. Franks.

The undermentioned appts. are made:—

To be Lts. (Temp. Commns.).—Harbans L. Khosla, Nisar Mohammad Durrani, Suraj Prakash Wanchoo, Sharad Chandra Misra, and Shri Rameshwar.

The undermentioned officers have vacated appts.:—

A.D.M.S.—Col. G. A. D. Harvey, C.M.G., V.H.S., Brit. Serv.

D.A.D.P.—Maj. A. D. Loganadan, I.M.S.

COLONIAL MEDICAL SERVICE

Dr. N. J. Dias has been appointed Government medical officer, British Guiana, and Dr. T. A. Redhead and Dr. J. E. Ross medical officers, Grenada. Dr. J. R. Forde becomes senior medical officer, Gold Coast; Dr. J. H. Pottinger senior medical officer, Palestine; Dr. A. M. W. Rae senior medical officer, Gambia; Dr. C. F. Deutrom superintendent and quarantine medical officer, Mandapam, Ceylon; and Dr. S. T. Gunasekera deputy director of medical and sanitary services, Ceylon.

SCOTLAND

(FROM OUR OWN CORRESPONDENT)

VOLUNTARY HOSPITALS

Prof. J. M. Munro Kerr, president of the Royal Faculty of Physicians and Surgeons of Glasgow, in an address on hospital development delivered last week, said that sooner or later voluntary hospitals would be faced with the problem of paying their surgical and medical staffs. Medical men as well as many members of the general public felt that it would be very unfortunate if the voluntary hospitals ceased to exist as entities. Hospital development was in a state of evolution, and it was difficult to foretell how the position of the voluntary hospitals and those under the control of local authorities would be affected. It appeared to many people that the only way by which the identity of the voluntary hospitals can be preserved is an expansion of the paying block system. The Victoria Infirmary was an example of successful development along these lines, and the Glasgow Royal Infirmary was embarking on a similar scheme. This would have the effect of removing the less efficient nursing-homes of which there are a great number. It was now difficult for young men to specialise because hospital appointments are unpaid, and Prof. Kerr had heard recently of promising young specialists who had been obliged to give up on account of this difficulty. In some hospitals two-thirds of the running costs were paid by the paying block, and he believed that the large voluntary hospitals could in this way be made almost self-supporting, while the physicians and surgeons would be satisfied with the arrangement. For the past 10 or 15 years many medical men had been trying to impress upon directors of voluntary hospitals that this would be their salvation. If the developments they advised were carried out, he thought that the voluntary hospitals would be in such a strong position that there would be no danger of the local health authorities taking control of them.

HOURS OF ASYLUM STAFF

The Fife Joint Asylum committee last week decided to recommend that the hours of duty of the staff at Springfield Asylum should be reduced to 48 per week. The application for a reduction in hours was made by the Mental Hospital and Institutional Workers' Union, and the report submitted showed that the staff at present have a 12-hour day and a 60-hour week. The proposed alteration was supported by the medical superintendent. The recommendation will entail an additional cost of nearly £3500 per annum, and the nurses' home will have to be extended. The £65,000 hospital extension scheme at the asylum has been agreed to, and at a meeting of the committee on May 8th it was decided to obtain competitive plans for the work.

THE MEDICAL CURRICULUM

LINES OF REFORM

TO-DAY appears the report of a conference which has met from time to time since December, 1932, to consider defects in the medical curriculum and ways in which they may be overcome.* Its authors begin by pointing out that despite its imperfections the present curriculum is capable of producing well-trained and efficient practitioners of medicine. Their preponderance, however, depends on inherent qualities as much as on training. The more intelligent student is never likely to be handicapped by the faults of a curriculum so much as his less gifted brother or sister. But the intention should be to give the student of average ability such knowledge and such education as will enable him to approach the problems of practice with some degree of confidence and put him in a position to learn from subsequent observation and experience. A scientific outlook, once acquired, will prove of more lasting value than a store of knowledge; at the same time it is impossible to inculcate general scientific principles without the introduction of many facts.

The conference has felt unable to recommend changes which would prolong the present minimum period of five years for a medical qualification. It has aimed instead at changes which will make it a continuous period of study, as little broken up by examinations as possible, affording the student time and opportunity for self-education in spite of the efforts he is called upon to make in memorisation. It is hoped that under this régime his memory may prove equal to its burden, and that by developing at all points fields of association his mind may acquire that kind of culture which survives the forgetting of facts.

Pre-medical Studies

The conference found that its dislike for early specialisation was shared by the scholastic profession. That a boy who has reached matriculation standard should spend his last two years at school almost wholly in the study of the natural sciences may not be undesirable, although it is important that the study of literature and languages should be continued up to the time of leaving. But it is a serious matter if intending medical students during their last two years are segregated in a small group, not only from the rest of the school, but even from other boys on the science side. The existence of "M.B. classes" at schools—small groups of boys who are engaged, not so much in the study of science, as in working through a prescribed syllabus in preparation for a series of small examinations—is a very unfortunate result of the present system. If all schoolboys and girls devoted a reasonable proportion of their time throughout the school period to the natural sciences there should be less need for a prolonged period of intensive preparation at the end of school life.

* The members are Sir FARQUHAR BUZZARD, Dr. M. H. MACKEITH, and Mr. W. H. OGILVIE (representing the University of Oxford); Sir WALTER LANGDON-BROWN, Prof. H. R. DEAN and Dr. A. E. CLARK-KENNEDY (University of Cambridge); Dr. A. M. H. GRAY, Prof. G. E. GASK, Prof. C. A. LOVATT EVANS, and Prof. WINIFRED CULLIS (University of London); Lord DAWSON OF PENN, Sir RAYMOND CRAWFURD, and Sir EWEN MACLEAN (Royal College of Physicians of London); Sir HOLBURT WARING, Prof. WILLIAM WRIGHT, and Mr. E. L. PEARCE GOULD (Royal College of Surgeons of England); Mr. T. B. LAYTON (Society of Apothecaries of London); and Prof. W. W. JAMESON (London School of Hygiene and Tropical Medicine). Lord Dawson has acted as chairman, and Mr. G. W. Rossetti as secretary, while Sir Farquhar Buzzard has presided over the executive committee consisting of Prof. Gask, Dr. Clark-Kennedy, Prof. Dean, Prof. Lovatt Evans, Mr. Pearce Gould, Dr. Gray, Dr. MacKeith, Sir Ewen Maclean, and Prof. Wright.

the principles of general pathology, immunology, and bacteriology. This proposal is made not with a view to initiating the student into the problems of clinical medicine but to enable him to appreciate the relevancy of his laboratory observations and experiments to the structure and function of the living human body. At this stage the student should begin to practise the use of the stethoscope, ophthalmoscope, and otoscope, and should gain experience of the relation of "physical signs" to the normal structure and function of the organs of the body.

Anatomy.—The conference has devoted earnest attention to the large proportion of the student's time which is spent in the dissecting room, and has considered a suggestion that it is unnecessary for every student to dissect the whole body. On this important question unanimity has not been reached. On the other hand, it takes the view that while dissection is valuable as a training in technique and a discipline, it can with advantage be supplemented by the use of models, by radiography, and by other methods. The teacher of anatomy could save the student's time if he had the opportunity of demonstrating the anatomy of the abdomen and thorax in the post-mortem room, and he should also be given access to hospital material for teaching applied anatomy, with or without the assistance of a clinician attached to his department.

In the past, it is felt, too much time has been spent and too great a stress has been laid on the memorisation of structural detail for examination purposes. It is therefore recommended that the student's acquaintance with the details of each part immediately after its dissection should be established orally by his teachers before he is allowed to proceed to the next, but the retention in his memory of all such minutiæ should not be made the criterion of his fitness to pass on to hospital work.

Histology.—The idea prevalent in some medical schools that the object of histology is "to spot the organ" by a hasty glance down the microscope should be discouraged. The conference is of opinion that the student should have a practical knowledge of the more important methods by which material is prepared for microscopical examination, but thinks there is a tendency to spend too much time in the practice of technical details. The teaching of morbid histology would be made somewhat easier if during the teaching of normal histology the attention of the student were drawn from time to time to specimens illustrating the changes resulting from the reaction of tissues to chemical and physical influences.

Organic and Physical Chemistry.—The growing importance of a knowledge of chemistry in physiology, pathology, and medicine is universally recognised. Not only organic chemistry but physical and colloidal chemistry are essential for the medical student, and further instruction in chemistry is clearly necessary after passing the 1st M.B. The conference holds that the teaching in this subject should be determined by conference in which the teachers of physiology, biochemistry, and chemistry meet together, due weight being given to the opinions of the teacher of physiology on the special needs of students of medicine. A special examination in organic chemistry is unnecessary, but questions in organic and physical chemistry should be included in the pre-clinical examination in physiology and biochemistry.

Physiology.—It is now an increasing and commendable practice in medical schools to lay stress on the physiology of man. The significance of these lessons, however, is often not realised and the med student fails to recognise their import when h faced with their clinical applications. It is at stage that coöperation with the clinical staff n prove essential. The object to be aimed at is t the head of the physiology department should h access to patients or command the services of so member of the clinical staff to give appropri demonstrations. It should be made clear that student at this stage is not in this way to rece instruction in medicine but in physiology. should be shown patients, not as examples of disea however typical, but as examples of deranged fu tion, such as jaundice, œdema, cyanosis, breathle ness, or paralysis.

Pharmacology.—A knowledge of the physiologi action of drugs is of primary importance to t student, and the conference believes that a sh course of lectures and practical work on this subj is essential. While there should be no separ examination the candidate's knowledge should tested either by the inclusion of pharmacologi questions in the physiology paper and in the pra tical examination or by a viva-voce examinatio A knowledge of doses should not be required from student before he begins his clinical work, and the pre-clinical teaching of pharmacology the ther peutic applications should be omitted except in far as they are necessary to illustrate importa principles.

Pathology.—As already indicated, the stude should be introduced to the elements of gener pathology, immunology, and bacteriology durin the last two terms of the pre-clinical period. Th object of this is to bring home to him the basi processes underlying the disorders of structure an function with which he is shortly to be faced at th bedside. The scope of this instruction should, o course, be a matter of agreement between the patho logist and physiologist, whose fields might otherwis overlap.

Psychology.—A course of about eight lecture introductory to the psychological aspects of medicin should be given during the last two terms of th second year. Attendance should be obligatory, bu no examination should be held at this stage.

THE PRE-CLINICAL EXAMINATION

The pre-clinical examination at the end o the second year of the curriculum should tes the student's general knowledge of the structure and functions of the human body and his acquaintanc with the principles underlying simple reactions o its tissues to chemical and physical changes in thei environment. The conference has been impressed by the high proportion of failures in examinations in anatomy and physiology, and believes that their number could and should be reduced, not by lowering the standard but by altering the methods of teaching and examination. Knowledge of detail should be tested orally by the teacher before passing on to a new part of the work, and success in the pre-clinical examination should depend not on a mere feat of memory but rather on such grasp of the structure and function of the body as is a necessary equipment for hospital work. Since instruction in elementary general pathology is to be included in the pre-clinical period the student's knowledge of this subject should be tested in the examination. The board of examiners should represent anatomy, physiology, pathology, and pharmacology, and they should meet and coöperate in setting their questions.

Clinical Period

The supreme value of periods of clerking and dressing in the general wards remains unchallenged. It must be recognised, however, that medicine is becoming, and should become, more scientific and less empiric. The scientific standards and methods of thought inculcated in the pre-clinical years should be carried into the wards and applied at the bedside and in the laboratory. For this reason it is hoped that applied physiology and anatomy will be carried through the whole of the medical course, and also that pathology will be taught throughout the clinical period, in close association with all the branches of medicine, and not be regarded as a special study.

There is in all large hospitals a mass of clinical material ready to hand for the study of minor ailments and much of this passes in and out of the casualty and out-patient departments unused. In special departments such as those dealing with the diseases of the eye, the ear, the nose, the throat, and the skin, the student may, under proper guidance, absorb a large amount of useful information and experience if he is encouraged to do so. But he knows that there is little likelihood of his being confronted with an "eye case" or a "throat case" in his final examination and is often content to run the risk of exposing his ignorance in these directions. The remedy appears to lie in having representatives of the special departments on the board of examiners, and the fear of their expecting too much specialised knowledge from students need not be entertained if they examine in association with general physicians and surgeons. On the other hand, their coöperation would lead to the newly qualified practitioner being more familiar with the use of instruments, such as the ophthalmoscope and the laryngoscope, and with common disorders of the sense organs which will form a big part of his work in general practice. Much of the time now spent in watching major operations might be more profitably used in attending the casualty department.

The teaching of *preventive medicine* will be adequate only if its importance is realised by teachers throughout the whole curriculum. The professor of physiology will demonstrate the scientific basis of personal hygiene; the teacher of pathology will emphasise the advances which have come from bacteriological and immunological research; the clinician will find innumerable opportunities for instruction in preventive medicine; while obstetricians and pædiatricians must explain the practitioner's functions in relation to such matters as antenatal work, the conservative conduct of labour, the management of the puerperium, and the care of the child in its early years. In addition a short course in public health and State medicine, including forensic medicine, should be given, mainly by a member of the public health service selected for his ability to teach. (The syllabus of such a course is outlined.) It is suggested that some of the lectures might be given by an experienced insurance practitioner, and some by a man skilled in medico-legal work.

Medical psychology has already been introduced to the student. Now, during the clinical years, he must become familiar with the psychological aspects of patients in the hospital, and with this object demonstrations should be held at least once a fortnight throughout the period of in-patient clerking and in-patient dressing. In every ward there are many patients suitable for teaching of this kind, and in some schools such demonstrations have long been in force with great success. The physician or surgeon in charge of the ward may undertake them himself or may hand over that duty to a colleague attached to the hospital for the purpose of teaching medical psychology. In this way the teacher of medical psychology may be able to draw upon the material in the hospital as a whole for teaching purposes, and by selecting patients whose condition is not primarily one of mental disorder he can bring the psychological features of illness to the student's notice. Besides such instruction attendance should be required at not less than six demonstrations at a mental hospital, where the student can observe the general aspects of advanced insanity, and the working of an institution for the care of the insane and mentally defective.

In the final qualifying examination adequate knowledge of the psychological aspects of ill-health should be expected from the candidates and should be thoroughly tested, not only in written papers but in the clinical and oral parts of the examination.

Pathology must be taught with two objects in mind. First, to give the student such a grasp of its importance that he will come to think at the bedside instinctively in terms of pathology, and, secondly, to give him such an interest in the science of pathology that he is alert to follow its progress and ready to avail himself throughout his career of the advances in pathological theory and their application. To ensure the latter the student must attend set courses in pure pathology and spend enough time in laboratory work to learn something of its technique and experimental methods. To provide for the former he must throughout his clinical course renew his acquaintance with morbid processes as they are associated with physical signs. The conference is of opinion that the student will be helped to grasp the true importance of pathology and its bearing upon his practice if the examination in this subject —instead of being something separate, which can be passed and left behind—is made part of the final examination.

FINAL EXAMINATION

There is much to be said for a final examination in pathology, medicine, surgery, and obstetrics, the whole to be passed at one time. But experience has shown that few students are able to do themselves justice in so stern a test; and while it is very desirable to preserve the unity of pathology, medicine, and surgery by combining them in one examination, it is felt that obstetrics, gynæcology, and disorders of infancy might well be taken separately. Modern conditions of practice make the recently qualified practitioner a consultant in obstetrics, and for this reason it would in fact be a real advantage if the test of knowledge in this subject were made the last step in the whole curriculum. And to a certain extent the same may be said of public health and State medicine.

The conference therefore recommends that the final examination should consist of two parts:—

I. Medicine, Surgery, and Pathology.

II. Gynæcology, Obstetrics, and Pædiatrics; Public Health and State Medicine, including Forensic Medicine.

Both parts may be taken at the same time, or a candidate may enter for Part I. alone; but no one will be held to have passed Part II. until he has passed Part I. The examination will include a test of the student's knowledge of the physiological and therapeutic aspects of pharmacology (including toxicology).

The final examination, it is suggested, should be conducted by a board of examiners who are to meet and coöperate in setting questions so that the papers are reasonably balanced. The pass list should be prepared at a meeting of the board at which all are present. The examiners in Part I. might include representatives of: medicine, surgery, pathology, medical psychology, dermatology, ophthalmology, oto-rhino-laryngology, and orthopædic surgery (including manipulative surgery); and in Part II.: *obstetrics and gynæcology, pædiatrics and disorders* of infancy, and public health and State medicine (including forensic medicine). The conference is agreed that such a board would secure a better all-round education for the medical student, by a more thorough test of his knowledge of general medicine and surgery, without in any way adding to its difficulties. And incidentally it recommends that more time should be allowed for the clinical and viva-voce parts of the examination than is usually given at present.

Post-graduate Clinical Experience

The conference holds that a medical student after passing the final examination should spend at least *six months as a resident medical officer in an approved* hospital before entering on private practice. It hopes that in the near future the number of such posts available to recently qualified men and women may be sufficient to make a statutory obligation of this kind practicable.

CORRESPONDENCE

SERUM IN STREPTOCOCCAL FEVERS

To the Editor of THE LANCET

SIR,—For some years I have been advocating a much more cautious and conservative attitude with regard to the use of serum in streptococcal fevers. It was therefore with interest and approval that I read the important paper by Dr. Leonard Colebrook in the current issue of THE LANCET and your own commentary upon it. In the Guy's Hospital Reports (1931, lxxxi., 1) I wrote a paper with Dr. R. E. Smith on the Natural History, Prognosis, and Treatment of Streptococcal Fever, in which we came to the same conclusions as Dr. Colebrook, (*a*) on analysis of my own experience in hospital and private practice and during the war, and (*b*) on analysis of the cases of *streptococcal septicæmia treated* in Guy's Hospital over a period of ten years. The prolonged and indiscriminate employment of serum without checks or controls and without any sound proofs of efficacy ever being produced is only another example of the unsatisfactory and unscientific tendencies in the therapeutics of the last few decades.

The older physicians frequently preferred to study and learn the natural course of a disease before making claims on behalf of new remedies. We should to-day make much more steady progress if we would but take a lesson from them. The example of Gull in my own school who was at pains to report on a series of cases of rheumatic fever "treated with mint water" as an answer to those who made extravagant claims for their "cures" might well be more frequently followed. It is surely a reflection on our methods that we have continued for forty years to employ expensive preparations, capable of producing unpleasant symptoms and even of causing adverse effects at times, on the basis of entirely haphazard and uncorrelated clinical trials and without any collective investigation. It has been the same story with vaccine and endocrine therapy.

I am, Sir, yours faithfully,
JOHN A. RYLE.

London, W., May 11th.

THE PROBLEM OF DIPHTHERIA

To the Editor of THE LANCET

SIR,—All the points which Dr. Stallybrass has raised in his letters to THE LANCET of March 23rd and May 4th have been covered to the best of my ability in the criticised report itself and my letter in THE LANCET of April 13th. For example: (1) The extra *invasiveness of gravis* diphtheria bacilli is considered on page 37 of the report and in my last letter. (2) The weakness of the statistics which Dr. Stallybrass objects to is admitted in the letter and discussed on page 39 of the report. (3) The ratio of virulent to avirulent carriers, and the possible effect of immunisation on this ratio, is given on pages 45, 46, and 102. (4) The relative risk to the herd and individual of contracting diphtheria from cases and carriers is argued on page 100 of the report. Dr. Stallybrass is incorrect in stating that we used chocolate media to isolate diphtheria bacilli after immunising the school. This medium was only used to confirm the Leeds workers' observations; plain serum-agar was preferred by us and used both before and after the immunisation of Greenwich Hospital School in 1928.

I would not have trespassed further on your space, but on behalf of my colleagues I felt it only fair to try to correct the impression which is conveyed by Dr. Stallybrass's letters—to wit that the report contained irresponsible statements, which were made without full examination of the evidence which was available at the time it was produced. I feel horrified to think that anyone who took the trouble to read the *whole* report could imagine that the investigations in Greenwich Hospital School "constituted a crucial experiment." Almost ad nauseam the report was interspersed with cautions and examples against accepting the findings at this school as of general application everywhere else; for instances, among many others, see pages 46, 92, 100, and 127 of the report. I have ever distrusted "crucial experiments," especially in epidemiology, and as M. Greenwood has said, in better language than is at my command, of the type of reasoning which maintains that what happens in one environment will necessarily take place in another—"I do not know an uglier or more crippling fault in the statistical epidemiologist than to reason in such a way. It is almost, perhaps quite, as intellectually vicious as the *post hoc ergo propter hoc* of the unstatistically minded." In any case, should I have been guilty of this "crippling fault," Dr. Stallybrass is alongside me in the same boat, if he believes that the failure to discover a carrier among a "considerable number" of 200–300 children in one school sufficient justification for the inference that active immunisation will in general diminish carrier infection.

Finally, it is most interesting to learn that virulent carriers were probably as frequent among the Schick susceptibles as among the Schick immunes of a Liverpool institution, as this is another nail in the coffin of the dictum that the carrier of virulent diphtheria bacilli is always Schick negative—the dictum on which, as I stated in my letter of April 13th, the inference that active immunisation may increase the virulent carrier-rate largely depends. As Dr. Stallybrass says, on most points he and I are in complete agreement, but on the point in question we are probably both subconsciously biased and perhaps, therefore, both at fault. Of course, if so, our conscious mind would be unable to realise this, and hence we had better agree to differ as regards the effect of anti-diphtheria innoculations on the virulent carrier-rate. I am, Sir, yours faithfully,

SHELDON F. DUDLEY.

Medical Department, Admiralty, S.W., May 13th.

CONTINUOUS DRIP BLOOD TRANSFUSION

To the Editor of THE LANCET

SIR,—Dr. Garnett Sheldon expresses his hearty agreement with the open method of approach to the vein. While not disputing the possibility that this may be necessary in the continuous method described (of which I have no experience), I cannot but feel that this must be regarded as one of its most serious disadvantages. Many of the cases so treated must necessarily be in a position of needing a repetition of the operation, especially if it is to be of service in cases of severe aplastic anæmia. To deprive such a patient of his available veins one by one is the worst sort of policy. I have seen such patients rendered almost untransfusable by the process, and, until there is some evidence of permanent benefit from the continuous method, the "direct approach" should surely be discouraged.

Personally I can see no reason why an ordinary venepuncture needle should not be used—the more so as a rapid flow is not required—and I cannot agree that it is necessary to be an "expert" to insert one, even where the veins are small. In ordinary transfusions, at least, cutting down on the vein should be an emergency proceeding only. The Red Cross Society has wisely placed a ban on "direct approach" in the case of donors, and I cannot help feeling that persons unable to carry out a venipuncture should not be encouraged to attempt transfusions at all. I am, Sir, yours faithfully,

Grosvenor-street, W., May 8th. J. W. SHACKLE.

DISTRESS AND HEALTH

To the Editor of THE LANCET

SIR,—The annotation in your last issue hardly does justice to the White Paper Cmd. 4886. The investigators spent only 17 days on the inquiry. In this time they went to eight places, visited maternity and child welfare centres, schools, junior instruction centres, and homes of the people. They consulted eight categories of medical, educational, and social authorities, including 28 medical practitioners and 7 members of the staffs of voluntary hospitals. They examined over 700 toddlers, 935 school-children, 400 youths and girls at junior instruction centres, 159 women at antenatal clinics, 230 mothers of young children, and observed men attending a labour exchange. Few will dispute that their observations are based "not on exhaustive clinical examination," and that their conclusions should "be regarded as approximate rather than as of scientific accuracy;" few also will attach much significance to their findings.

The vital statistics of the area concerned, which the investigators quote, show a serious condition during the last five years, however much worse it may have been in the past. The infant mortality-rates of the areas given are some 30 per cent. above that of England and Wales. The death rates in Sunderland from bronchitis, pneumonia, and measles were 30, 70, and 300 per cent. respectively above those of England and Wales. The pulmonary tuberculosis death-rate in Sunderland for the age-group 15–24 years in the period 1931–33 was about 50 per cent. higher than in the period 1911–13. A similar increase has occurred in other areas where unemployment has been severe and prolonged, while during the same time the pulmonary tuberculosis death-rate of this age-group in England and Wales generally has fallen 20 per cent. for males and remained stationary for females.

To return to the clinical examination; the investigators learnt that no gross rickets was found among regular attenders at welfare centres. Had they prolonged their trip a few days they might have discovered another profound truth—that people who visit a dentist regularly rarely have neglected teeth. With the widespread knowledge of the treatment of rickets and the increased facilities available, few children are left to become badly deformed; but this does not exclude the occurrence of milder degrees of the disease, which are only detectable by thorough examination. What significance, then, can be attached either to the percentage of rickets detected in toddlers by the investigators' superficial examination, or to the incidence of "deformities due to rickets" among school-children? Numerous statements have been made to the effect that mild degrees of rickets are still very common. For example, the medical officer of health for Woolwich (not a poor or unhealthy borough) claimed that 30 per cent. of children attending the toddlers' clinic in 1933 were definitely rachitic. Dr. A. G. Hamilton, writing in THE LANCET on Feb. 2nd of this year, considered that rickets could be detected in not less than 50 per cent. of those who attend infant welfare centres. If these claims are correct they reveal a widespread incidence of a wholly preventable disease. The matter calls for investigation by the Ministry of Health. But such an investigation would involve something more than a 17-day campaign, and a cheap, if hollow, victory.

I am, Sir, yours faithfully,

Bishops Stortford, May 11th. JOHN MARRACK.

EFFECTS OF PITUITARY EXTRACTS ON BLOOD

To the Editor of THE LANCET

SIR,—In their stimulating contribution to your last issue (p. 1099) Prof. Dodds and his co-workers describe the remarkable effects of extracts of the posterior lobe of the pituitary on the blood of rabbits. It may be of additional interest to record the fact that alkaline extracts of the *anterior* pituitary also exercise a profound influence on hæmopoiesis in rabbits. Animals injected with such extracts over a period of a week or ten days invariably exhibit a marked hyperplasia of the bone-marrow at autopsy. Since this hyperplasia is somewhat similar in nature to that produced by thyroid medication, it would appear that in this instance the phenomenon is due to stimulation of the thyroid gland by the thyrotropic principle of the pituitary.

I am, Sir, yours faithfully,

Brentwood, May 14th. THOMAS D. POWER.

DR. STILL'S PRESENTATION PORTRAIT

To the Editor of THE LANCET

SIR,—Will you please allow me to say that the note in the Royal Academy catalogue in reference to Dr. Still's portrait is not intended to convey that it will hang in King's College Hospital. It is to be presented to Dr. Still, together with a list of subscribers to the fund, which is being kept open for a short time longer. All contributions, through the generosity of Mr. Gerald Kelly, R.A., the artist, are being devoted to the endowment of a cot in honour of Dr. Still. Contributions may still be addressed to the Treasurer of the Portrait Fund at this Hospital, and a list of subscribers will be presented to Dr. Still in due course.—I am, Sir, yours faithfully,

C. E. A. BEDWELL,
House Governor, King's College Hospital.
Denmark Hill, S.E., May 14th.

PREVENTION OF THE COMMON COLD

To the Editor of THE LANCET

SIR,—In your issue of April 13th (page 914) Dr. Ernest Ward says that there are a host of prophylactic measures, none of which can be relied upon for protection against the common cold. Has he ever tried thyroid for this purpose? I have never given thyroid simply for the prevention of colds, but its action in this respect has been observed when given for other purposes. The dosage has been calculated according to the pulse-rate, sometimes assisted by the patient's temperature. I was taking 2 grains a day and noticed that although I was attending patients with influenza (to which I have always been very susceptible) I have remained free from that complaint through several epidemics. Also I suffered from no severe cold during the winter —a most unusual occurrence. A man, aged 28, taking thyroid gr. ½ every day, suffered no severe cold all the winter—he usually has several feverish chills; he stated that a chronic nasal catarrh from which he suffers has greatly improved. A lady, aged 46, taking thyroid gr. 1 every night volunteered the statement that she had suffered much less from colds all the winter. A man, aged 48, taking grs. 2 of thyroid regularly has not called me in to attend him once during last winter; previously he has usually been incapacitated from his duties for about 10 days once or twice every winter with a catarrhal cold. And I could go on telling stories like this.

I am, Sir, yours faithfully,

May 13th. A LONDON G.P.

PARLIAMENTARY INTELLIGENCE

NOTES ON CURRENT TOPICS

Unemployment Assistance: Local Authorities Grants

ON May 9th in the House of Commons Sir HILTON YOUNG, Minister of Health, moved the second reading of the Unemployment Assistance (Temporary Provisions) (No. 2) Bill. The proposal was to put local authorities as far as possible in the same position after March 1st as they would have been if March 1st had been retained as the appointed day under the Unemployment Act of 1934. In order to do that they must clearly estimate the local authorities' expenditure on the relief of the class in question, and they must ascertain what contribution they would have made to the board under the financial scheme of the original Bill. In order to safeguard the local authorities the Bill provided that the duration of the agreed basis was to be either until the second appointed day was actually determined or for a limited period of six months. The amount of expenditure of which local authorities were being relieved was £6,000,000 a year, while the amount of their contributions was only £2,000,000 a year, so that there was a positive benefit to the local authorities on this transaction of no less than £4,000,000 a year. Liverpool would get assistance equivalent to a 2*s.* 7½*d.* rate; Sunderland a 2*s.* rate; Merthyr Tydvil a 2*s.* 9*d* rate; and taking the country as a whole the equivalent of a 3½*d.* rate was the average assistance to all local authorities.—Mr. A. GREENWOOD moved the rejection of the Bill on the ground that it failed to give effect to the principle that the entire cost of maintaining unemployed persons who are not in receipt of unemployment benefit should be a national charge.—The motion for the rejection of the Bill was negatived by 152 votes to 49, and the Bill was read a second time.

Public Health Services in India

In the House of Commons on May 13th the Government of India Bill was further considered in Committee. Mr. H. WILLIAMS moved to omit public health and sanitation from the list of subjects to be dealt with by the provincial legislatures. After discussion this amendment was negatived by 216 votes to 31.

Voluntary Hospitals and Paying Patients

In the House of Lords on May 14th the Voluntary Hospitals (Paying Patients) Bill was considered in Committee.

Viscount GAGE (Lord-in-Waiting) explained that on the second reading the Government had expressed general sympathy with the objects of the Bill, but they felt that in granting new powers in an Act there ought to be careful provision that the original intentions of existing trusts were preserved. The Government felt that the safeguards in the Bill could and should be strengthened. They had been in close touch with representatives of the hospitals in all matters concerning amendments and, except in one particular, there had been agreement.

Lord MACMILLAN moved to amend paragraph (2) of Clause 2 (accommodation for and charges to paying patients) so that it would read that the committee of management might charge such patients for accommodation, treatment, and maintenance (including such medical and surgical attendance and treatment as was given by the resident staff of the hospital) in accordance with such scale of charges as might be specified in any order made by the Charity Commissioners. He said that the amendment was designed to meet the wishes of certain medical associations. It was felt that provision should be made for a tariff which would cover all the expenses incurred by the hospitals. The amendment had been moved, after consultation with the British Medical Association, to remove any ambiguity with regard to fees to be charged.

The amendment was agreed to.

Viscount GAGE moved a new clause making provision for patients able to make some but not full payment. He said that if such patients were admitted to the free wards of certain hospitals it was doubtful whether that could be done legally, and it could not be done under certain trusts. It was obviously desirable that the hospital accommodation should be available to such persons. The clause made it obligatory on the Charity Commissioners, unless they thought it would be unappropriate in the case of a particular hospital, to reserve a certain amount of accommodation for such persons. The amount to be reserved would vary with different hospitals. The scale of charges specified in an order would include charges fixed with a view to meeting the needs of patients who, though able to make some payment, were unable to pay charges sufficient to meet the full expense to the hospital.

The Earl of DUDLEY said that while he agreed with the necessity for the new clause he hoped that the Government realised that the cheaper beds, for instance the four-guinea beds for which Lord Gage was seeking to make ample provision, were largely carried by the more expensive or ten-guinea beds. If the Charity Commissioners restricted the number of the more expensive beds it would be impossible to maintain the four-guinea beds, and the hospitals would be driven to adopt a one-standard seven-guinea bed. He hoped it would be made quite plain that there was no intention to restrict the more expensive beds.

The clause was read a second time and added to the Bill.

Viscount GAGE moved a new clause containing provisions for the protection of existing trusts. He said that the first part of the clause which was agreed between the Government and the promoters indicated the conditions under which the Charity Commissioners might make an order allowing land belonging to hospitals to be used for erecting new wards or buildings for paying patients. It was provided that the use of the land was only to be authorised if the Commissioners were satisfied that it would not be required for the purposes for which the trusts were created until after the expiration of a substantial period. The second part of the clause was the only point on which the Government and the promoters had not been able to come to an agreement. As he understood it, the promoters thought that in certain cases it might be possible by rearrangement of the wards and minor structural alterations to provide extra accommodation within existing buildings for paying patients. They were quite ready to give safeguards to protect whatever number of poor patients' beds they might happen to have and to see that none of those poor patients should suffer in regard to space or treatment through this rearrangement. But they claimed that, providing no reduction of numbers was occasioned, they had the right to use the new accommodation for paying beds. The Government claimed that if by the rearrangement of certain buildings it was possible to provide additional beds the poorer class of patient had the right under most of the trusts to those extra beds, if the funds permitted. If any other form of wards could be devised to get over the difficulty the Government would consider it very carefully.

Lord MACMILLAN said he shared Lord Gage's satisfaction at the large measure of agreement which had been achieved in carrying through this very beneficial measure. He regretted that they were not entirely agreed. In regard to existing buildings, the clause was not really satisfactory. In many hospitals it would be possible by an internal arrangement at a relatively small expenditure to get additional space to accommodate a limited number of patients to whom charges could be made. It would not be possible to do that under the clause unless the hospital could show that it was short of funds, or that there was a shortage in demand for accommodation. Either or both of those things might be very difficult to prove in many instances.

Viscount HAILSHAM (Secretary of State for War) said that the Government agreed that where there were in existing buildings beds, these could not be diverted to other uses unless the conditions of the Bill were satisfied. Lord Macmillan and Lord Luke, however, wanted the Bill to allow the Charity Commissioners to say that where there were existing buildings, which had been erected by money provided for the express purpose of giving free medical or surgical help to the poor, these might be adapted to hold more beds than at present, and that the surplus beds might then be used for paying patients, notwithstanding the fact that there was money available to the hospital to use them as free beds and that there were poor people unable to pay anything who would like to avail themselves of those free beds. Those responsible for advising the Government took the view that where buildings had been provided for the very poor people who could pay nothing, and where there were very poor people who needed the help of the hospital and there was no room for them at present, if it were possible by arrangement of the existing building to provide extra accommodation, that accommodation was earmarked and devoted for the purpose for which the buildings were erected—the purpose of providing free help to the poor. Lord Macmillan, on the other hand, contended that if the rearrangement was achieved by money obtained from outside sources, then the extra accommodation so provided might be used for patients against whom a charge was to be made. This was a matter of principle and the Government did not feel it would be right to allow the extra beds in the existing buildings which were provided for the very poor to be used for any other purpose.

Lord LUKE said he hoped that before the Report stage the Government might find some form of wards which would meet the difficulty.

Viscount HAILSHAM said if the clause were allowed to pass in its present form the noble lord would not be prejudiced in any discussion which might take place between him and the Government on the matter.

The clause was agreed to, as was also an amendment by Lord Luke to the effect that the Bill should not apply to Scotland.

The Committee stage of the Bill was concluded.

HOUSE OF COMMONS

WEDNESDAY, MAY 8TH

Treatment of Disabled Pensioners

Mr. GUY asked the Minister of Pensions what was the future policy of his department with regard to the treatment of disabled pensioners; and whether it was intended that the existing hospital organisation would be continued permanently in its present form.—Major TRYON replied: It is the policy of the Ministry of Pensions to continue the existing practice of utilising those hospitals most suited to the interests of ex-Service patients for whom the Ministry is responsible. There is no intention of curtailing the special facilities provided by the Ministry except in so far as may prove to be justified by the natural decline in the medical work of the department.

Mansion House as Convalescent Home

Mr. LEONARD asked the Secretary of State for Scotland if he would give particulars of the large mansion house on the island of Raasay owned by the Department of Agriculture; how many rooms were in the house and whether they were furnished; how many acres of land were attached as policies and gardens ground; how long had these subjects been owned by the State; to whom were they now let; what was the total annual gross average receipts from these subjects, including sporting rental; what were the total annual average payments, including wages to gamekeepers, gardeners, rates, and general upkeep; and whether he would consider in future using this mansion house as a hostel, guest house, or holiday home for sick persons, and operated by approved societies, or otherwise.—Sir G. COLLINS replied: Raasay estate, including the mansion house, was acquired by the department at Candlemas, 1922. The house contains 45 rooms, with domestic offices, and is furnished. The garden and policies extend to about 15⅛ acres. The house is normally let along with the sporting rights, but has not yet been let for the coming season. The average annual gross receipts from lets in recent years amounted to approximately £310. The average annual expenditure on wages, rent, and general upkeep has been approximately £390. With regard to the last part of the question, although the house provides the only accommodation on the island for a tenant of the sporting subjects, I shall give consideration to any proposals submitted by approved societies for utilising the house in the manner indicated by the hon. Member.

Disease Carrier—Iver Heath

Mr. Groves asked the Minister of Health whether the order for the removal to hospital of the cattleman at Iver Heath was obtained by the medical officer of health from magistrates sitting in public or privately from one magistrate.—Sir Hilton Young replied: I understand that this order was issued by a single justice.

MONDAY, MAY 13TH

Ex-Service Men and Epilepsy

Mr. Hall-Caine asked the Minister of Pensions the number of applications made by ex-Service men for pensions in respect of epilepsy which they attributed to their war service, and in how many cases pensions had been granted.—Major Tryon replied: I have no record of the number of claims for pension that have been made in respect of epilepsy. The aggregate number of pensions that have been granted in respect of this disease is 8412.

Detention of Disease Carrier at Iver, Bucks

Sir Arnold Wilson asked the Minister of Health whether he was aware that W. Barrett, a cattleman at Dromenagh Farm, Iver, Bucks, had been detained since March 12th in the isolation hospital at Cippenham on the unsupported statement of a single medical officer that he was suffering from an infectious disease, though he was at that date, and was now, considered by another doctor to be free from any disease; and whether he would procure his immediate release without prejudice to any claim he might put forward for damages for illegal detention.—Mr. Shakespeare replied: My right hon. friend understands that the man referred to was not detained in the isolation hospital on the unsupported statement of a single medical officer, but that eight consecutive bacteriological examinations of swabs taken from his throat disclosed the presence of hæmolytic streptococci. My right hon. friend is informed that he was discharged from hospital as soon as bacteriological examination indicated that the organisms were no longer present.

Sir Arnold Wilson asked the Minister of Health whether his attention had been drawn to the statement at pages 96 to 98 of the Report on the Health of the Army for 1932, that no appreciable decrease in the total dysentery figures had occurred during the five years in which an extensive search for dysentery carriers had been in operation, and that routine investigation for carriers had been abandoned in view of the injustice entailed to individuals; and whether, in view of the fact that hæmolytic streptococci, which were the cause of the isolation of a cowman at Cippenham Isolation Hospital, were frequently found in healthy persons, he would institute inquiries with a view to preventing injustice to individuals in such cases.—Mr. Shakespeare replied: The answer to the first part of the question is in the affirmative, but my right hon. friend is advised that dysentery is not comparable with the streptococcal infections, and that the isolation of the man referred to in the second part of the question was, in the circumstances of the case, the proper course. He was isolated not merely because of the finding of certain organisms in his throat, but as a result of a combination of bacteriological findings and epidemiological evidence. My right hon. friend sees no necessity for special inquiries on this subject.

Soldier's Detention in Mental Hospital

Mr. Thorne asked the Secretary of State for Scotland if he could give the House any information in connexion with the case of John Mulholland, late private in the Highland Light Infantry, who was at present an inmate of the Lochgilphead Mental Hospital; whether any application had been received for the release of this man, who was stated to be sane; and what action he proposed to take in the matter.—Sir Godfrey Collins: I have made inquiry and find that Mr. John Mulholland has been an inmate of the Argyll and Bute District Asylum at Lochgilphead, under a sheriff's order, since Dec. 28th, 1934. When admitted he was suffering from epilepsy and mental confusion. No communication regarding his discharge has been received by the General Board of Control for Scotland. I am taking immediate steps to have further inquiries made into the circumstances of the case. In the meantime I may say that Mr. Mulholland's mental state and general health have considerably improved during his residence in the asylum.

TUESDAY, MAY 14TH

Medical Examinations of Army Officers

Captain Cunningham-Reid asked the Financial Secretary to the War Office (1) how many officers of the rank of colonel and of each rank of general officer had, during the past 12 months, been found not to be fit in all respects for active service; and how many of those so found unfit were still on full pay; and (2) whether all colonels and general officers had been medically examined during the past 12 months; and, if so, whether any reductions in the ages for compulsory retirement of colonels and the various ranks of general officers were contemplated as a result of these medical examinations.—Mr. Douglas Hacking replied: With the permission of my hon. and gallant friend, I will answer this question and No. 2 together. All general officers and colonels who are employed on full pay have been medically examined during the last 12 months. Four officers of these ranks were found by medical boards to be unfit, and only one of them remains on full pay. Officers found to be temporarily unfit are removed to the half-pay list when they have exhausted their sick leave or are pronounced permanently unfit for general service. No reductions in the ages for compulsory retirement of officers of these ranks are contemplated.

Reconditioning of Houses

Mr. Joel asked the Minister of Health whether the Government had ever considered the desirability of making a grant for the reconditioning of houses, both by local authorities and by private owners; and what were its views on this subject.—Mr. Shakespeare replied: Yes, Sir. The Government have given careful consideration to this question, and are of the opinion that the needs of the situation will be adequately met by the Housing (Rural Workers) Acts, 1926–1931, as proposed to be amended by the Housing Bill now before Parliament and by the general provisions of that Bill.

Imports of Processed Milk Products

Sir Percy Hurd asked the Minister of Agriculture whether, in view of the increased production of milk this summer and the greater output of condensed milk and dried milk in this country, the Government was taking further steps to check by quantitative restriction or tariffs the importations of processed milk products.—Mr. Elliot replied: The Governments of the foreign countries mainly concerned in the United Kingdom market with condensed milk, milk powder, and cream have been asked to arrange for certain additional reductions in supplies as from April 1st last, the reductions in each case being based on imports during the corresponding months of the year previous to the introduction of voluntary import regulation—namely, June, 1932, to May, 1933. Arrangements are also being made to secure reductions in imports of condensed whole milk, condensed skimmed milk, and cream from the Irish Free State. As my hon. friend will be aware, imports of processed milks from foreign countries are already subject to customs duties. It is understood that the interests concerned have under consideration an application to the Import Duties Advisory Committee for additional duties on condensed skimmed milk, condensed whole milk, and milk powder (the duty on cream has been conventionalised under the Anglo-Danish Trade Agreement which operates until June, 1936). If such an application is made, future policy will be considered in the light of any recommendations received from the Import Duties Advisory Committee. The following statement gives details of the reductions referred to above:

Condensed skimmed milk: 10 per cent. (making 40 per cent. in all) during the six months to Sept. 30th. Condensed whole milk: 5 per cent. (making 35 per cent. in all) during the quarter ending June 30th, and a further 5 per cent. during the quarter ending Sept. 30th. Milk powder: 5 per cent. (making 30 per cent. in all) during the quarter ending June 30th, and a further 5 per cent. during the quarter ending Sept. 30th. Cream: 5 per cent. (making 40 per cent. in all) during the quarter nding June 30th, and a further 5 per cent. in each of the quarters ending Sept. 30th and Dec. 31st.

Pensioners and Disseminated Sclerosis

Mr. HUTCHISON asked the Minister of Pensions whether ny pensions had been granted to applicants suffering from disseminated sclerosis attributed to war service; and, if so, whether he could give the numbers of such pensions.—Major TRYON replied: Pensions have been granted in a certain number of cases for the disease referred to, but I am unable to quote figures as they are not separately classified in the records of the Ministry.

MEDICAL NEWS

Royal College of Surgeons of England

At a meeting of the council of the college held on May 9th, with Sir Holburt Waring, the president, in the chair, Dr. W. T. Gordon Pugh and Mr. H. E. G. Boyle, members of 20 years' standing, were admitted to the fellowship.

Mr. C. Bowdler Henry was appointed as the representative of the college at the ninth international dental congress to be held in Vienna in August, 1936. Mr. G. C. Knight and Dr. D. Slome were reappointed Leverhulme scholars for a third year from July 1st. The president reported that he performed the opening of the new building of the Royal Australasian College of Surgeons in Melbourne on March 4th, and that he presented to Mr. E. S. J. King the certificate of the award to him of the Jacksonian prize for 1933. Diplomas of membership were granted to the following candidates in addition to those mentioned in our issues of May 4th and 11th:—

H. F. Anderson, Camb. and St. George's; Margaret Brodigan, Univ. Coll.; J. E. Elliott, Guy's Hosp.; and K. D. Gibson, Camb. and St. George's.

A diploma in gynæcology and obstetrics was granted jointly with the Royal College of Physicians, to Roland Hodgson Nattrass.

University of London

On May 20th and 27th, at University College Hospital medical school, at 5.15 P.M., Prof. Charles Singer is giving two further lectures on the history of medicine. On May 20th he will speak on recent additions to the history of syphilis, and on May 27th on medicine in America.

University of Glasgow

The Struthers gold medal and prize has been awarded to Dr. Thomas Nicol, lecturer in regional anatomy in the University.

University of Manchester

Dr. H. L. Sheehan, lecturer in pathology, has resigned his post on his appointment as director of the research department in the Glasgow Maternity Hospital.

International Association of Thalassotherapy

The seventh congress of this association will be held at San Sebastian from July 27th to 30th. The chief subjects of discussion will be the treatment of cervical adenitis, and the indications and contra-indications of sun-bathing. Information may be had from the organising committee, Asociación Internacional de Talasoterapia, Plaza del Buen Pastor, 20, San Sebastián, Guipúzcoa, Spain.

Lebanon Hospital for Mental Diseases

The thirty-sixth annual meeting of this hospital will be held at Friends House, Euston-road, London, N.W., on Monday, May 20th, at 4.30 P.M., when Lord Alness will be in the chair. The speakers will include Dr. Percy Smith.

Lincoln County Hospital

It is hoped to open the first of the new wards built under the extension scheme before the end of June. The number of patients is steadily increasing, and in the first three months of the year the hospital dealt with 300 emergencies and accident cases.

Chadwick Public Lectures

A lecture on educational and preventive physical exercises will be given on Thursday, May 23rd, at 5.30 P.M., at Manson House, 26, Portland-place, London, W., by Miss Noel Tidy, and Sir James Crichton-Browne, F.R.S., will preside. On June 6th, at the Chelsea Physic Garden, Swan Walk, Chelsea, Sir John Russell, F.R.S., will speak on modern changes in food production and their influence on our sources of supply. These lectures have been arranged by the Chadwick Trust, and the secretary may be addressed at 204, Abbey House, Westminster, S.W.1.

Royal College of Physicians of Edinburgh

A quarterly meeting of the College was held on May 7th with Dr. Edwin Bramwell, the president, in the chair. Dr. Alexander Hay Rintoul (Crieff) was elected a Fellow of the College. The Freeland Barbour fellowship was awarded to Mr. R. R. Goodall.

Royal Medico-Psychological Association

The ninety-fourth annual meeting of the association will be held from July 3rd to 5th, at 11, Chandos-street, London, W., and the guildhall of the Middlesex county council, Westminster, S.W. Visits have been arranged to Springfield Hospital and Shenley Hospital. The secretary is Dr. Reginald Worth, Springfield Mental Hospital, near Tooting, London, S.W. 17.

Royal Sanitary Institute

Immunisation in theory and practice, and housing with special reference to overcrowding, will be discussed at a sessional meeting of this institute to be held in the Town Hall, Carlisle, on Friday, May 24th. The first discussion will be introduced by Dr. J. Steven Faulds and Dr. J. C. B. Craig, and the second by Dr. Allan Semple, medical officer of health of Carlisle, and Mr. W. Hanson. Particulars may be had from Dr. Semple.

University of London Medical Graduates Society

The annual dinner of this society was held at the Langham Hotel on May 7th, Mr. McAdam Eccles presiding. Before grace, a message of loyal congratulation was sent to T.M. the King and Queen on the occasion of their Silver Jubilee. The toast of the society was proposed by the president, who announced a great increase in membership during the past year, and said he would be meeting London medical graduates at every port of call on his journey to and from Melbourne. Sir Charlton Briscoe responded in a humorous speech. The guests of the evening were the dean and the professorial staff of the British Postgraduate School at Hammersmith. In proposing their health, the president paid tribute in turn to the qualities of Col. Proctor, Prof. Fraser, Prof. Grey Turner, Prof. Young, and Prof. Kettle. Prof. Fraser, in replying, outlined the schemes proposed for the instruction of every type of medical graduate from home and abroad.

University of Sheffield

The council of the University has invited Dr. H. N. Green, at present lecturer in pathology in the University of Cambridge, to succeed Prof. Florey in the chair of pathology.

Dr. Green was educated at the University of Sheffield where he has the degrees of M.D. and M.Sc. Qualifying in 1924 he held several resident appointments at the Sheffield Royal Infirmary. On joining the pharmacological department under Prof. Edward Mellanby, he became interested in nutritional problems and was associated in Mellanby's work on calcification and on vitamin A in relation to infection. This led to a study of the vitamin A content of human liver in puerperal sepsis, reported in THE LANCET in 1932. Latterly Dr. Green has been demonstrator in pathology in the University of Cambridge, and his investigations of vitamin A deficiency have given rise to research into fat metabolism and serum esterase, a recent paper being concerned with changes induced by cancer and carcinogenetic agents.

Mr. A. C. W. Hutchinson, dean of the Edinburgh Dental Hospital and School, has been appointed professor of dental surgery; Dr. R. E. Pleasance, honorary lecturer in anæsthetics; and Dr. W. J. Clancy, honorary demonstrator in obstetrics. Dr. Dorothy Brown has resigned her post of lecturer in bacteriology; Dr. Percival Hay his post of lecturer in ophthalmology; and Dr. B. D. Pullinger her post of demonstrator in pathology.

Kent and Canterbury Hospital

The Duke of Kent has promised to lay the foundation-stone of this hospital on Friday, July 12th.

Sir Ernest Graham-Little has been elected for the ninth time in succession to represent medical graduates of Convocation upon the Senate of the University of London.

Dr. Lawson Gifford and Dr. T. J. Hallinan have been appointed members of the Legislative Council of the Island of Jamaica.

Bolingbroke Hospital

The rebuilding scheme of this hospital is to cost £70,000; that there is sometimes a waiting list of 250 for admission to the wards demonstrates its urgency. A sum of £10,000 has been collected, and King Edward's Hospital fund has promised £1000. The old mansion part of the building continues to deteriorate.

Ear, Nose, and Throat Congress in Vienna

The first congress of the Austrian otolaryngologists will be held in Vienna on June 21st and 22nd. Prof. M. Hajek (Vienna), Prof. G. Hofer (Graz), Prof. W. Krainz (Innsbruck), and Prof. H. Neumann (Vienna) will take the chair at the various sessions. The subjects of discussion will include vertigo, otogenic meningitis, postanginal complications, and new methods of speech training. The secretary of the congress is Ernst Urbant Schitsch, Wien, I., Schottenring 24.

Inter-State Post-Graduate Medical Association of North America

Some 30 members of this body are paying a visit to London at the end of May. Visits have been arranged for them to the Middlesex Hospital on Monday, May 27th, to Guy's Hospital on May 28th, and to St. Bartholomew's Hospital on the 29th. At this last meeting, which will take place in the afternoon, a special programme of clinical demonstrations has been arranged. Mr. Philip Franklin (27, Wimpole-street, W.1) is in charge of the clinical arrangements.

St. John's Hospital for Diseases of the Skin

New premises for out-patients are to be provided at Lisle-street, Leicester-square, and should be open by the end of the year. The landowners of the present out-patient department are prepared to allow the hospital the sum of £23,500 for the surrender of the lease of the building, leaving about £10,000 to be raised to prepare and equip the new department. The work of the electro-therapeutic department has been much extended.

Carnegie Grants for Medical Work

Eight Carnegie grants have been awarded to South Africa for 1935–36, and two of the recipients are medical men. Dr. D. L. Ferguson, medical officer of health for Port Elizabeth, will study the national and municipal control of food supplies, with especial reference to milk and pasteurisation, and the housing of the poorer classes, especially where two or more races are involved. Dr. C. C. P. Anning, M.O.H. for Pietermaritzburg, is to investigate the administration and practice of tuberculosis control, and the training of non-Europeans in hygiene and sanitation.

Mosquito Day

On Monday last Mosquito Day was celebrated by a luncheon in honour of Patrick Manson and Ronald Ross, held at the London School of Hygiene and Tropical Medicine. Since the amalgamation of the Ross Institute with the School it has been considered fitting that the name of Manson should be linked with that of Ross in holding what has been for some years an annual celebration, and the day will in future be May 13th. Sir Austen Chamberlain, chairman of the governors of the School, who presided, spoke of the foundation of the Institute and of the School, and of the work which both were doing in the control of malaria. He recalled that his father, Joseph Chamberlain, had sought out Manson to be his medical adviser at the Colonial Office. Sir George Newman, speaking as the oldest personal friend of Sir Ronald Ross present at the gathering, said he could name no other discovery of life-saving value which had been so promptly appreciated by the persons interested. It had been shown that the work of science could be translated both into the saving of lives and the economic production of rubber and tea.

Queen's University, Belfast

Colonel S. H. Browne, a graduate of the old Queen's College, Belfast, and formerly of the Indian Medical Service, has left a legacy of £10,000 to the University to found a scholarship for the promotion of medical research in the university. The amount and conditions of the awards will in due course be determined by the academic authorities.

New Hospital for Leek

The growing population of Leek is demanding a new hospital to relieve the pressure on the North Staffordshire Royal Infirmary. The weekly cost per occupied bed was £2 18*s.* 10*d.*, and the deficit on the hospital's general account is £532.

Derbyshire Royal Infirmary

The work of this hospital continues to increase; the daily average of beds occupied is 331, which is the highest on record. The wards are overcrowded, and it is hoped to begin on the new building scheme shortly. Mr. J. H. Thomas has given £1000 for the endowment of a bed to commemorate his silver jubilee as Member of Parliament for Derby.

Medical Prayer Union

The annual medical missionary breakfast of the union will be held at the Refectory, University College, Gower-street, on Wednesday, May 29th, at 8 A.M. The chair will be taken by Mr. W. McAdam Eccles, and an address given by Dr. Fredk. N. Green of the Church Missionary Society, Maseno, E. Africa. Those wishing to attend should notify the hon. secretary, Dr. Tom Jays, Livingstone College, Leyton, E.10.

Mount Vernon Hospital

Last year 673 persons were admitted to the wards but the hospital's activities are seriously handicapped by lack of money, and it will be impossible to increase the number of occupied beds until the radiological department has been enlarged and additional apparatus provided. This would cost £10,000, and another £10,000 is needed for maintenance. The income fails to meet expenditure by £5000.

International Society of Medical Hydrology

The annual meeting of this society will be held in Brussels from Oct. 12th to 17th. On Oct. 13th a discussion on the action of carbon dioxide baths on the peripheral circulation will be opened by Dr. E. Guilleaume and Dr. Marcel Wybauw (Belgium), Dr. P. N. Deschamps (France), and Prof. H. Vogt and Dr. R. Wachter (Germany), while on Oct. 14th Prof. Scherbakov (Jugoslavia), Prof. S. Pisani (Italy), and Prof. V. Mladejovsky (Czechoslovakia) will speak on the therapeutic action of muds. On the two following days a visit will be made to Luxembourg to inspect the establishments at Mondorf and Spa. On Oct. 17th a third medical discussion on therapeutic agencies of the sea coast will be held at Ostend, and papers will be read by Prof. I. Gunzburg (Belgium) and Dr. W. G. Willoughby (Great Britain). The secretary of the society may be addressed at 109, Kingsway, London, W.C.2.

Congress of Gastro-enterology

The first international congress of gastro-enterology is to be held in Brussels from August 8th to 11th, under the presidency of Dr. M. J. Schoemaker, of the Hague. The members will meet in sections of medicine, surgery, radiology, and pathology, and in addition there will be two general meetings, for discussion of gastritis and severe ulcerative colitis (non-amœbic). An international society of gastro-enterology will, it is hoped, be founded. The secretary-general of the congress is Dr. Georges Brohée, 64, Rue de la Concorde, Brussels. An English committee has been formed, with Sir William Hale-White and Dr. A. F. Hurst as honorary president and president respectively. The other members are Dr. Adolphe Abrahams, Dr. T. L. Hardy, Mr. John Morley, Dr. J. W. McNee, Dr. J. A. Ryle, Dr. C. K. Simpson, Sir Edmund Spriggs, Prof. W. W. D. Thomson, Mr. A. J. Walton, and Prof. D. P. D. Wilkie. Dr. Thomas Hunt (12, Queen Anne-street, London, W.) is the hon. secretary.

Medical Congresses in Brussels

The Journées Médicales de Bruxelles will be held this year from June 29th to July 3rd under the presidency of Dr. Edgard Zunz, professor of pharmacology of the faculty of medicine. The main subject of discussion is to be the physiopathology of the endocrine glands, and Prof. George Barger (Edinburgh) will be among the speakers. The secretary of the congress is Dr. R. Beckers, 141, rue Belliard, Brussels. As already announced, the meeting of the Belgian Society for Physical Education will also take place at the same time (June 30th to July 3rd).

From Sept. 12th–19th the Tomarkin foundation is arranging to hold its seventh international medical post-graduate congress in Brussels. The lecturers will include Sir Crisp English, U. Friedemann, J. Plesch, and W. Levinthal (London), C. Heymans (Ghent), A. S. Hyman (New York), J. Schwartzmann (Odessa), M. Ascoli (Palermo), C. Regaud, N. Fressinger, A. Besredka, C. Levaditi, and M. P. Weil (Paris), E. Loewenstein (Vienna), P. Ulenhüth (Freiburg), and A. J. D. Cameron (Tunbridge Wells). The secretary of the foundation may be addressed at the Faculty of Medicine, 97, Rue aux Laines, Brussels.

Fellowship of Medicine and Post-Graduate Medical Association

Courses will be given in gynæcology at the Chelsea Hospital from May 27th to June 8th; in chest diseases, City of London Hospital, Victoria Park, from May 27th to June 1st; in venereal disease, London Lock Hospital, from May 27th to June 22nd; in chest and heart diseases at the Victoria Park Hospital (6 P.M. on Wednesdays and Fridays) from June 5th to 28th; in chest diseases at the Brompton Hospital (at 5 P.M on two days a week) during June. There will also be a clinical and pathological course at the National Temperance Hospital at 8 P.M. Tuesdays and Thursdays, from June 11th to 28th. Week-end courses will be given as follows: obstetrics at the City of London Maternity Hospital, May 25th and 26th; fevers at the Park Hospital, Hither Green, June 15th and 16th. Other forthcoming courses include urology at St. Peter's Hospital, June 17th to 29th; medicine, surgery, and the specialties at the Prince of Wales Hospital, June 17th to 29th and July 1st to 13th; cardiology at the National Heart Hospital, June 24th to July 6th. Daily clinical instruction in various branches of medicine and surgery is available through a panel of teachers. A supper-dance and cabaret has been arranged to take place at Claridge's on Wednesday, June 5th, at 9.30 P.M. Tickets can be obtained from the Fellowship, 1, Wimpole-street, W. 1.

Medical Diary

SOCIETIES

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

Tuesday, May 21st.

Special Meeting of Fellows. 5 P.M. *General Meeting of Fellows,* 5.30 P.M.

Wednesday.

Comparative Medicine. 5 P.M. (Royal Army Medical College, Grosvenor-road, S.W.), Annual General Meeting. Demonstrations: G. R. Cameron and W. A. E. Karunaratne: Liver Changes in Exophthalmic Goitre. W. A. E. Karunaratne: Rhinosporidiosis in Man. C. L. Oakley: Tuberculosis in the Dog. E. S. Duthie: Mitochondria and Cell Survival. J. A. Boycott: Agglutination Reaction in Glandular Fever. G. H. Eagles: Spontaneous Encephalitis in the Monkey. Also demonstrations by E. L. Taylor, E. Klieneberger, J. R. M. Innes, J. A. Nicholson and J. Stewart, E. J. Pullinger, and A. W. Stableforth.

Thursday.

Urology. 8.30 P.M., Annual General Meeting. Discussion on the Scope and Indications for Renal Sympathectomy, to be opened by Mr. S. Harry Harris (Sydney).

Friday.

Disease in Children. 5 P.M., Annual General Meeting. Cases: Dr. Raymond Kirk (for Dr. G. Bray): 1. Urticaria Pigmentosa of the Nodular Type. Dr. John Gibbens: 2. Malignant Tumour of the Liver ? secondary to a Suprarenal Tumour. Dr. Branford Morgan: 3. Coarctation of Aorta, with unusual Radiological Shadow. Dr. R. Bailey (for Dr. D. Paterson): 4. Tumour of the Left Iliac Fossa.

Epidemiology and State Medicine. 8 P.M., Annual General Meeting. Dr. Gordon Pickles: Epidemiology in Country Practice.

MEDICO-LEGAL SOCIETY.

Thursday, May 23rd.—8.30 P.M. (11, Chandos-street, W.), Dr. T. H. Blench: A Police Surgeon's Problems.

ST. JOHN'S HOSPITAL DERMATOLOGICAL SOCIETY, 49, Leicester-square, W.C.

Wednesday, May 22nd.—4.30 P.M., Clinical Cases.

CHELSEA CLINICAL SOCIETY.

Tuesday, May 21st.—8.30 P.M. (Hotel Rembrandt, Thurloe-place, S.W.), Dr. Millais Culpin: Sex Problems in Practice.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF PHYSICIANS, Pall Mall East, S.W.

Tuesday, May 21st.—5 P.M., Sir Edmund Spriggs: A Clinical Study of Headaches. (Last Croonian lecture.)

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

Monday, May 20th, to Saturday, May 25th.—Maudsley Hospital, Denmark-hill, S.E. Afternoon course in psychological medicine.—St. John's Hospital, Leicester-square, W.C. Afternoon course in dermatology. (*Open to all.*)—Gordon Hospital, Vauxhall Bridge-road, S.E. All-day course in proctology.—City of London Maternity Hospital, City-road, E.C. Week-end course in obstetrics.—Courses arranged by the Fellowship are open only to members and associates.

WEST LONDON HOSPITAL POST-GRADUATE COLLEGE, Hammersmith, W.

Monday, May 20th.—10 A.M., Medical and Surgical Wards, Genito-urinary Operations, Skin Clinic. 2 P.M., Gynæcological and Surgical Wards, Eye and Gynæcological Clinics.

Tuesday.—10 A.M., Medical Wards. 11 A.M., Surgical Wards. 2 P.M., Nose, Throat, and Ear Clinic. 4.15 P.M., Dr. Redvers Ironside: Coma.

Wednesday.—10 A.M., Medical Wards, Children's Wards and Clinic. 2 P.M., Gynæcological Operations and Eye Clinic.

Thursday.—10 A.M., Neurological and Gynæcological Clinics. 12 noon, Fracture Demonstration. 2 P.M., Genito-urinary and Eye Clinics. 3.45 P.M., Venereal Diseases Clinic.

Friday.—10 A.M., Skin Clinic. Noon, Lecture on Treatment. 2 P.M., Throat, Nose, and Ear Clinic. 4.15 P.M., Mr. Roche: Urethral Stricture.

Saturday.—10 A.M., Medical Wards, Children's and Surgical Clinics.

Daily at 2 P.M., Operations, Medical and Surgical Clinics. The lectures at 4.15 P.M. are open to all medical practitioners without fee.

ST. MARY'S HOSPITAL, W.2.

Thursday, May 23rd.—5 P.M. (Institute of Pathology), Dr. C. H. Andrewes: The Cancer Problem: Some Fresh Clues.

LONDON SCHOOL OF DERMATOLOGY, 49, Leicester-square, W.C.

Monday, May 20th.—5 P.M., Dr. H. D. Haldin-Davis: Drug Eruptions.

Tuesday.—5 P.M., Dr. J. E. M. Wigley: Napkin Area Eruptions.

Thursday.—5 P.M., Dr. A. C. Roxburgh: Differential Diagnosis of some Common Skin Diseases.

Friday.—5 P.M., Dr. W. J. O'Donovan: Tuberculosis of the Skin.

CENTRAL LONDON THROAT, NOSE, AND EAR HOSPITAL, Gray's Inn-road, W.C.

Monday, May 20th, to Saturday, May 25th.—Intensive Clinical Course. (Second week.)

HOSPITAL FOR EPILEPSY AND PARALYSIS, Maida Vale, W.

Thursday, May 23rd.—3 P.M., Dr. Douglas McAlpine: Demonstration.

HOSPITAL FOR SICK CHILDREN, Great Ormond-st., W.C.

Thursday, May 23rd.—2 P.M., Dr. B. E. Schlesinger: Endocrine Disorders. 3 P.M., Dr. D. N. Nabarro: Meningitis: (2) Treatment.

Out-patient clinics daily at 10 A.M. and ward visits (except Wednesday) at 2 P.M.

NATIONAL INSTITUTE OF INDUSTRIAL PSYCHOLOGY.

Monday, May 20th.—5.30 P.M. (London School of Hygiene and Tropical Medicine, 1, Keppel-street, W.C.), Prof. M. Greenwood, F.R.S.: Temperaments, Physical and Psychological, in Modern Science.

INSTITUTE OF MEDICAL PSYCHOLOGY, Malet-place, W.C.

Wednesday, May 22nd.—3 P.M., Dr. H. Crichton-Miller: Hysteria. 4.30 P.M., Dr. Cedric Shaw: Cardiovascular Syndromes.

ROYAL INFIRMARY, Manchester.

Tuesday, May 21st.—4.15 P.M., Dr. N. Kletz: On Constipation.

Friday.—4.15 P.M., Dr. J. Wharton: Demonstration of Ophthalmic Cases.

UNIVERSITY OF BIRMINGHAM.

Tuesday, May 21st.—3.30 P.M. (General Hospital), Mr. H. H. Sampson: Demonstration of Surgical Cases.

Wednesday.—3.30 P.M. (Anatomy Theatre, The University), Dr. Howard Co[illegible] ic Toxins.

Friday.—3.30 P.M. [illegible] T. S. Donovan: Fractures and [illegible]

UNIVERSITY OF DURHAM COLLEGE OF MEDICINE.

Sunday, May 19th.—10.30 A.M. (Newcastle General Hospital), Dr. F. J. Nattrass: Medical Ward Visit.

GLASGOW POST-GRADUATE MEDICAL ASSOCIATION.

Wednesday, May 22nd.—4.15 P.M. (Royal Infirmary), Dr. David Smith: Medical Cases.

ROYAL INFIRMARY, Dundee.

Thursday, May 23rd.—3.15 P.M., Dr. J. Thomson: Diseases of Children, Clinical Cases. 4.15 P.M., Dr. W. L. Kinnear: Diseases of Children: the Treatment of some Pulmonary Affections.

Appointments

BLATCHLEY, DONALD, M.B. Edin., has been appointed Hon. Anæsthetist to the Hospital for Women, Soho-square.

CHAMINGS, A. J. WILSON, F.R.C.S. Eng., Hon. Laryngologist to the Woolwich and District War Memorial Hospital.

LESLIE, W., M.B. Lond., F.R.C.S. Eng., Senior Assistant Medical Officer (Grade I.) to St. Luke's Hospital, Chelsea.

ORD, J. W. E., M.D. McGill, Hon. Anæsthetist to the Willesden General Hospital.

PARKER, G. E., F.R.C.S. Eng., Surgical Registrar to the Woolwich and District War Memorial Hospital.

Middlesex County Council.—The following senior medical appointments at County hospitals are announced:—

BIRCH, C. A., M.D. Liverp., M.R.C.P. Lond., Senior Physician, North Middlesex;
GALLOWAY, R. L., M.B., F.R.C.S. Edin., Senior Surgeon, North Middlesex;
HUDSON, K. A., M.B. Sydney, M.C.O.G., Senior Obstetrician, North Middlesex;
JACKSON, E. B., M.D., M.R.C.P. Lond., Physician, Hillingdon;
JAMES, T. G. ILLTYD, M.Ch. Wales, F.R.C.S. Eng., Senior Surgeon, Central Middlesex;
JOULES, HORACE, M.D., M.R.C.P. Lond., Senior Physician, Central Middlesex;
NELSON, T. S., B.M. Oxon., F.R.C.P. Lond., Senior Physician; West Middlesex;
ROSSER, E. AP I., M.R.C.S. Eng., Obstetrician, Redhill.
STERN, D. M., M.B. Camb., F.R.C.S. Eng., Obstetrician, West Middlesex; and
WEBB, C. H. S., M.S. Lond., F.R.C.S. Eng., Senior Surgeon, West Middlesex.

Medical Referee under the Workmen's Compensation Act, 1925: Dr. R. C. **AITCHISON**, of Selkirk, for the Selkirk Sheriff Court District (Sheriffdom of Roxburgh, Berwick, and Selkirk).

Certifying Surgeons under the Factory and Workshop Acts: Dr. D. C. **PIM** (Abergavenny District, Monmouthshire).

Vacancies

For further information refer to the advertisement columns

Aberdeen Royal Infirmary.—Two Hon. Clin. Tutors.
Acton Borough Education Committee.—Asst. School M.O., &c. £550.
All Saints' Hospital, Austral-street, S.E.—Res. H.S. At rate of £100.
Antrim C.C.—Chief Tuber. M.O. £750.
Barnsley, Beckett Ho [illegible] s. O. £250.
Barnstaple, North De [illegible] At rate of £150.
Bath, Royal United [illegible] ıd Cas. O. £150. Also Hon. Surg. for Ear, Nose, and Throat Dept., and Hon. Med. Reg.
Beckenham, Bethlem Royal Hospital, Monks Orchard.—Radiologist. 150 guineas.
Bedford County Hospital.—First and Second H.S. At rate of £155 and £150 respectively.
Birmingham, Selly Oak Hospital.—Res. Physician. £650.
Bolton Royal Infirmary.—Two H.S.'s. Each £125.
[illegible] *National Sanatorium for Consumption, &c.*—
[illegible] *Sanatorium.*—Asst Res. M.O. £175.
Brighton, New Sussex Hospital for Women, Windlesham-road.—H.P. £100.
Brighton, Royal Alexandra Hospital for Sick Children.—H.S. £120.
Buxton, Devonshire Royal Hospital.—H.P. £200. Also Asst. H.P. At rate of £150.
Canterbury, Kent, and Canterbury Hospital.—Two H.S.'s. Each at rate of £125.
Cardiff, Welsh National School of Medicine.—Jun. Asst. in Medical Unit. £250.
Charing Cross Hospital, W.C.—Asst. Physician. Also Hon, First Asst. for Orthopædic Dept.
Chelsea Hospital for Women, Arthur-street, S.W.—Jun. H.S. At rate of £100.
City of London Hospital for Diseases of the Heart and Lungs, Victoria Park, E.—H.P. At rate of £100.
Coventry and Warwickshire Hospital.—H.S. for Aural and Ophth. Depts. At rate of £125.
Derbyshire Royal Infirmary.—Ophth. H.S. and Anæsthetist. £150.
Ealing Borough.—Asst. M.O. £450.
Elizabeth Garrett Anderson Hospital, Euston-road, N.W.—Clin. Asst. to Ear, Nose, and Throat Dept. Also H.P., three H.S.'s, and Obstet. Asst. Each at rate of £50.
Evelina Hospital for Sick Children, Southwark, S.E.—H.P. Also H.S. Each at rate of £120.
Golden-square, Throat, Nose, and Ear Hospital, W.—H.S. At rate of £100.
Grimsby Corporation Hospital.—Res. M.O. £350.
Hartlepools Hospital.—H.S. At rate of £150.
Hastings, Royal East Sussex Hospital.—Jun. H.S. At rate of £150.
Hertford County Hospital.—Sen. H.S. At rate of £200.
Hospital for Consumption and Diseases of the Chest, Brompton, S.W.—Asst. for Dept. of Pathology. £350. Also Asst. Physician.
Hospital for Sick Children, Great Ormond-street, W.C.—H.P. and H.S. Each at rate of £100.
Hull Royal Infirmary.—Cas. O. At rate of £150.
Indian Medical Service.—Commissions.
Iraq Government.—Appointments. Each £100–£120 per mensem.
Jersey General Hospital and Poor Law Infirmary.—Res. M.O. £100–£200.
King George Hospital, Ilford.—Res. Surg. O. and Res. Asst. Surg. O. £300 and £250 respectively. Also Two H.P.'s and Three H.S.'s. Each at rate of £100.
Lancaster, County Mental Hospital.—Asst. M.O. £500.
Lincoln City.—Deputy M.O.H. £600.
Lincoln County Hospital.—Jun. H.S. At rate of £150.
Liverpool Royal Babies' Hospital.—Res. M.O. At rate of £90.
Liverpool Sanatorium, Delamere Forest, Frodsham.—Second Asst. to Med. Supt. £200.
Liverpool [illegible] Reg. £50.
London [illegible] —Surg. Reg. £100.
London [illegible] en Travelling Studentship. £450.
Macclesfield General Infirmary.—Second H.S. At rate of £150.
Manchester Ear Hospital.—Res. H.S. £120.
Manchester Royal Infirmary.—M.O. to Out-patients. £35.
Manchester, Withington Hospital and Institution.—Jun. Asst. M.O. At rate of £200.
Manchester and Salford Hospital for Skin Diseases, Quay-street.—Two Asst. M.O.'s. Each £100. Also H.S. At rate of £100.
Margaret-street Hospital for Consumption, W.—Hon. Dental Surgeon.
Margate, Royal Sea Bathing Hospital.—H.S. At rate of £200.
Middlesbrough, North Riding Infirmary.—Third H.S. £125.
Middlesex County Council.—Dist. M.O. £75. Also Public Vaccinator.
Miller General Hospital, Greenwich-road, S.E.—Out-patient Officer and Two Cas. O.'s. Each at rate of £150. Also H.P. and H.S. Each at rate of £100.
Newcastle-upon-Tyne Eye Hospital.—Jun. Res. H.S. £150.
Newcastle-upon-Tyne, Royal Victoria Infirmary, &c.—Temp. Asst. in [illegible] —£600.
North [illegible] *re Centre, Telford-road, W.*—M.
Norwic [illegible] Asst. School M.O. £500.
Notting [illegible] —Locum Tenens M.O. £7 7s. per week.
Oxford, [illegible] *spital.*—H.S. £100.
Padding [illegible] -Res. Med. Supt. £1100.
Plymou. [illegible] *Devonport.*—H.P. and Cas. O. At rate of £100. Also Res. Surg. and H.S. At rate of £200 and £120 respectively.
Queen Mary's Hospital for the East End, E.—Res. M.O. and Two Cas. O.'s. Each £150. Also Two H.S.'s., H.P., Obstet. H.S., and Res. Anæsthetist. Each £120.
Queen's Hospital for Children, Hackney-road, E.—H.P. and Cas. O. Each at rate of £100.
Radium Institute, Riding House-street, W.—H.S. At rate of £150.
Reading, Royal Berkshire Hospital.—Hon. Asst. Surgeon. Also H.S. for Ophthalmic, &c., Dept. £125.
Rhondda U.D.C.—Sen. Asst. M.O. for Maternity and Child Welfare Work. £700. Also Temp. Asst. M.O. £10 per week.
Royal Chest Hospital, City-road, E.C.—Res. M.O. Also H.P. At rate of £150 and £100 respectively.
Royal Free Hospital, Gray's Inn-road, W.C.—First Asst. in Children's Dept. At rate of £115. Res. Cas. O. at rate of £150. Also First H.S. and Res. Anæsthetist.
Royal Northern Hospital, Holloway, N.—Radiologist. £580.
Royal Waterloo Hospital for Children and Women, Waterloo-road, S.E.—Cas O. £200. Also H.S. At rate of £100.
Ryde, Royal Isle of Wight County Hospital.—Res. H.S. At rate of £180.
St. George's Hospital, S.W.—Asst. Physician.
Sheffield, Jessop Hospital for Women.—Three H.S.'s. Each at rate of £100.
Sheffield Royal Hospital.—Clin. Asst. to Ear, Nose, and Throat Dept. £300.
Sheffield Royal Infirmary.—H.P. At rate of £80.
Sheffield Royal Infirmary a [illegible] Clin. Asst. £300. £500.
Sheffield University.—Asst [illegible] tal O.
Singapore, King Edward [illegible] and Lecturer in Dental Mechanics. $500 per mensem.
Southend-on-Sea General Hospital.—Med. Reg. £300. Surg. Reg. £250. Also H.S. to Orthopædic and Casualty Dept. At rate of £100.
South London Hospital for Women, Clapham Common, S.W.—H.P. and H.S. Each at rate of £100.
South Shields [illegible] —Sen. and Jun. H.S.'s. £200
[illegible] —H.S. £160.
[illegible] —H.S. At rate of £150.
Talgarth, South Wales Sanatorium.—Asst. Res. M.O. £200.
Truro, Royal Cornwall Infirmary.—H.S. £170.
University College Hospital, Gower-street, W.C.—Hon. Asst. Physician.
West End Hospital for Nervous Diseases, Regent's Park.—Hon. Anæsthetist.
West London Hospital, Hammersmith-road, W.—Chief Clin. Asst. in X Ray Dept. £125.
Weston-super-Mare General Hospital.—Res. H.P. £150.
Windsor, King Edward VII Hospital.—Res. M.O. £150.
Wolverhampton Royal Hospital.—H.S. At rate of £100.
Wolverhampton and Midland Counties Eye Infirmary.—H.S. £150.
Woolwich and District War Memorial Hospital, Shooters Hill, S.E. H.P. and H.S. Each at rate of £100.
Worksop, Victoria Hospital.—Two Residents. At rate of £150 and £120 respectively.
York City.—Sen. Asst. School M.O. Also Asst. school M.O. Each £500. Also Temp. Asst. M.O. £500, and Temp. Res. M.O. £250.

The Chief Inspector of Factories announces vacant appointments for Certifying Factory Surgeons at Lowestoft, Suffolk; and Loughborough, Leicestershire.

NOTES, COMMENTS, AND ABSTRACTS

THE MEDICAL STUDENT ON HIS TRAINING

IN the council chamber of B.M.A. House fifty medical students from various London schools met on Tuesday evening, at the invitation of the U.C.H. Medical Society, to debate the motion: "The inadequacy of medical education lies in the curriculum." Participation in this debate was limited to unqualified students, but Sir Ernest Graham-Little was in the chair, and three deans occupied places in the front row and listened with bland appreciation to criticisms of their teaching programme. For them the sting was mitigated by the disclaimers on the part both of opener and opposer of the motion that while, on the motion, they must speak mainly of grievances they were not unappreciative of efforts made by deans and others. They admitted they were not well read in the principles of medical education, and not knowing what the future had in store for them their views must be largely conjectural.

With that preface, as the opener remarked, "we let ourselves loose and say what we like," and he started himself with an attack on the division of the six years' course into three years' pre-clinical and three years' clinical. Did not the student, he asked, learn incomparably more in the clinical years? It seemed to him futile to start on a wide if somewhat dilute scientific basis. Some preliminary education in elementary science was no doubt desirable, but why concentrate on the curious copulations of the earthworm; and was a particular knowledge of mechanics necessary in order to assemble axis-traction forceps? Normal anatomy and physiology were not of any interest to the medical man except as modified by disease. A pineal body that never went wrong could be ignored for medical practice, and he made a special plea for extension of the clinical years, as he believed diagnosis to be a matter of developed intuition. Speaking as a musician he could diagnose music where others could diagnose motor-cars, neither being able to say how. The skilful diagnostician, he contended, knows from the look of the thing just like any connoisseur. Get in contact early with clinical medicine was his message. A little access to the wards will give nodding acquaintance with a rather forbidding terminology, and help to make anatomy live in surgery and physiology in medicine.

His opposer opened by postulating the inadequacy of all medical education and began an analogy between teaching and digestion which ran like a streak all through the subsequent discussion. What was wrong was not the pabulum but the ability to assimilate it. If we regard our teachers, he said, as the liver ("some are definite gallstones") then examiners are the kidney, with a threshold at times too low for the attractive substances offered by examinees. A later speaker would have it that the student body was suffering from a surfeit of fat things which no amount of bile will help him to assimilate. The opposer found fault not with the curriculum but in turn with the student, the teacher, and the examiner. Many students start too young; they come to medical schools having been spoon-fed, and few know how to work. The teacher should teach the student how to think: he was too apt to teach medicine and surgery but not how to be a physician or surgeon. No change in the curriculum could teach a man to think. That lay in the rôle of teacher who alone could produce an attitude of mind.

All through the evening arose again and again this criticism of the teacher and the examiner. The examiner was not necessarily qualified to examine or to form a true estimate of a candidate's work. He would not care himself to sit for examination in subjects other than his own. The first remark heard by a student on entering the wards was often: "If you had said that in an examination you would be referred for six months." This kind of playing up to examinations was harmful. The G.M.C. in 1922 had added four more subjects to the curriculum, apart from the emphasis on the preventive aspect of medicine. All these were added at the expense of apprenticeship in medicine, making the student's life one constant rush. Why, asked one speaker, were only 50 unqualified students present at this discussion? The rest were carefully learning facts at home. "We learn too much and know too little," he said. "This cannot go on."

An outline was given of a curriculum in which three years were spent on the principles of medicine for an academic degree not qualifying for practice, followed by two years of clinical work in one or other of the main faculties, with a diploma at the end entitling to practise; but the house was fairly equally divided in its preference for such an ad-hoc education over one in which the scientific principle was at the back of the programme in every year, and the student at liberty, as in the French system, to refresh his knowledge of anatomy and physiology at any time. There was profound disagreement about the position of preventive medicine in the curriculum. One side held that it could have little or no place in the training of the general practitioner; health could only be assessed by a study of deviations from the normal. Equally strenuous was the view that medicine is nothing if not applied physiology, and that the curriculum must be enlarged to include genetics and the results of industrial and environmental disease.

Throughout the discussion there was rather a pointed feeling of dissatisfaction with the character of the teaching itself. It was, said one, a bad day for the student when teachers in hospitals were voluntary. The attitude of the part-time teacher was: "Well, I'm obliging you, anyway." Everything was to be said for the unit system and the full-time teacher; "you can tell him what you want." But the meeting ended on a note of hopelessness in the prospect of change. Only students are interested in the curriculum; they alone can be the moving force in any change. But being very young, tactless, amenable to economic stress, and required to behave, what chance had he as a reformer?

To this Sir Ernest, in closing the meeting, remarked that students really had far more influence than that. They had, he thought, taken their share in bring about the report on the medical curriculum to be presented to the senate of London University the following day. He wished them success. The voting then taken gave 33 for and 18 against the motion, but the value of the evening was rather as a symposium than as a discussion.

RECREATIONAL GYMNASTICS

THE work of Miss Elli Björkstén is having a great influence upon the school and recreational gymnastics of this country; her methods are an adaptation especially for women and children of the Swedish traditional school.

In Part I. of her book on the principles of gymnastics for women and girls the broader outlines and theory of educational gymnastics with accompanying formal exercises were given; in Part II.[1] original game exercises for ages 8–13 years are planned on the basis of a four years' school training, and are grouped according to the movement classification of a normal gymnastic table. In a stimulating introduction, Miss Björkstén defines her aim as "ease combined with form." She discusses the use and abuse of rhythm and music in connexion with gymnastics; these are aids that are helpful only when they are used with discretion. A scheme is set out for the normal school gymnastic table of movements upon which these game-exercises are based. The table itself is too elaborate to be fitted into the time allotted to gymnastics in most schools.

---

[1] Principles of Gymnastics for Women and Girls. Part II. By Elli Björkstén, Senior Woman Teacher of Gymnastics at the University, Helsingfors. Translated by S. Kreuzer and G. H. Wicksteed. London: J. and A. Churchill Ltd. 1934. Pp. 591. 21s.

The fundamental standing position, rest, marching, and running, are then analysed with insistence upon lightness and elasticity as essential to the proper performance of all exercises. The rest of the work is devoted to the imaginative presentation of movements. For instance, "arm circling" is called the "small windmill"; a foot movement is pictured as "ski-ing down a steep hill"; various positions are named "the scarecrow," "the crane," "the chimney sweep"; and movements are given such suggestive titles as "Indians escaping in canoes," "Cossacks on horseback," and so forth. For fourth-year students jumps and elementary apparatus work are described in a more straightforward manner.

Teachers alert to find means of varying and adapting the presentation of their work to small children will find this book useful, and those whose duty it is to supervise remedial exercises may be stimulated to invent appropriate play exercises on the same lines. Backward and defective children especially need the imaginative and mental stimulus this type of teaching gives, and there is but little technical literature available on the subject of their physical training. It is unlikely that any teacher would care to follow the whole book; many will find in it stimulating ideas which will help them to enliven their class-work.

SANDOZ PRODUCTS

A PAMPHLET, published by J. Flint, Sandoz Products (134, Wigmore-street, London), sets out recent views on the use of calcium in inflammatory processes. The essay divides the indications for calcium therapy into those directed towards remineralisation in condition of calcium deficiency and those where transmineralisation is sought, the insoluble salt not being deposited as an inactive body but developing on its way through the organism. The effects of transmineralisation, using calcium in therapeutic doses, are set out in detail and elaborately documented; over 150 authors are cited in the pamphlet, and the large number of references make the value of experimental evidence clear to the reader.

The practical application of calcium therapy will, it is claimed, be greatly assisted by the use of preparations coming from the Sandoz Research Laboratories. Calcium-Sandoz is an organic calcium salt, an oxidation product of glucose, which is completely utilised by the organism, thus providing the maximum therapeutic action of the salt. It contains 9 per cent. of calcium. It is supplied in powder for oral administration and in tablets flavoured with chocolate or effervescent. Ampoules of 10 per cent. and 20 per cent. sterile solutions are suggested for intravenous and intramuscular injection. *Evidence is produced* that Calcium-Sandoz intramuscularly is painless and non-irritating, while intravenously it is better tolerated than the chloride. An interesting section of the pamphlet treats of the use of calcium in skin diseases, and allusion is made to the good results obtained by Trenk in a clinic at Munich which followed the use of Calcibronat in eczema, urticaria, pruritus, and varicose ulcers, the effect being particularly striking in urticaria. Calcibronat is a new organic salt, Ca-Br-Lactobionate $(C_{12}H_{21}O_{12})_2.Ca.CaBr_2+6H_2O$. and is designed to combine the sedative properties of a bromine-ion with Calcium-Sandoz.

A VERY GENERAL QUERY

A SUBSCRIBER writes to us in the following terms: "I shall be glad to hear from any subscribers who have had any reason whatever for being dissatisfied with any dealings involving time payments, or

in connexion with a publication." The writer the letter has discussed the situation with us hopes to get into touch with others who have recei unsatisfactory treatment from a particular fi Replies can be addressed to G.P., THE LANCET Off 7, Adam-street, Adelphi, W.C.2.

MICROSCOPES AND ACCESSORIES.—A catalogue reached us from Messrs. W. Watson and Sons, L London, describing instruments, optical compone and accessories manufactured by them. It encouraging to note in this thirty-fifth edition more attention is now being paid, by one of oldest makers of microscopes in England, to consistent production of high-grade apparatus. has not always been the position; English mal could often produce good microscopes, but t did not do so always and with certainty. Mod machine-tool methods are no doubt largely respons for the improvement, but unless these are accompa by stringent tests the results might still be irregu Messrs. Watson have evidently realised the importa of this with the result that their standard is both higher and more uniform. Practically ev application of the microscope in industry or scien research has been considered, and the informat contained in the catalogue will be of ser particularly to the novice.

Births, Marriages, and Deaths

BIRTHS

ATKINSON.—On May 6th, at Melton Mowbray, the wife M. W. Atkinson, M.R.C.S. Eng., of a daughter.

COOPER.—On May 6th, at Stafford, the wife of Thomas Valen Cooper, M.B. Lond., of a daughter.

GREGOR.—On May 8th, at Coventry, the wife of W. M.B. Aberd., of a son.

JAMES.—On April 30th, at Stoke Bishop, Bristol, of J. Angell James, M.D. Lond., F.R.C.S. En daughter.

MATTHEWS.—On May 7th, at Cowfold, Sussex, the T. E. Matthews, M.R.C.S. Eng., of a daughter.

QUINN.—On May 2nd, in London, the wife of Surg. Lt F. B. Quinn, M.B. N.U.I., Royal Navy, of a dau

SERGEANT.—On May 8th, a Hilton Sergeant, M.B.

STEPHENS.—On April 30th, Eng., of Ferguson-aven

MARRIAGES

BAMFORD—LEEMING.—On April 25th, at St. Cheltenham, J. Brian Bamford, of Ely, formerly of Kent, to Eileen Mary, daughter of Dr. Arnold of Cheltenham.

FYSH—CUMMINS.—On May 8th, at Maidenhead, Mark Fysh, M.R.C.S. Eng., to Eileen Alice, on the late Samuel Cummins and Mrs. Cummins Ireland.

MORRIS—MACDONNELL.—On April 27th, Lawre M.R.C.S. Eng., to Mai MacDonnell.

PIPER—HALL.—On May 11th, at the Parish C Middlesex, John Wesley Piper, M.R.C.S. E Mary Hall, only daughter of Mr. R. T. Hall

READING—SEERY.—On April 27th, at the Chur of Victories, Kensington, Philip Readi F.R.C.S. Eng., to Kathleen, eldest daug Patrick Seery and of Mrs. Seery, of Mulling

SEMON—PILCHER.—On May 2nd, at All Souls' Ch place, Henry C. Semon, M.D. Oxon., to Marjorie, eldest daughter of Captain Mansfield-street, W.

DEATHS

CONSIDINE.—On May 4th, suddenly, at Kill Co. Dublin, Thomas Ivoy Considine, F.R

JENNINGS.—On April 30th, at Southsea, Jennings, C.B.E., M.D., late A.M.S.

JEREMY.—On May 1st, at Colehill, Wimbor Jeremy, O.B.E., M.B. R.U.I., L.S.A., officer at the Memorial Hospital, Ludhiana.

MUSSEN.—On May 8th, at Chichester, William Mu Edin., late of St. Helens, Isle of Wight, aged

QUINTON.—On April 29th, at Winchester, Quinton, Surgeon-Captain, R.N. (retd.), seco late Dr. R. F. Quinton and of Mrs. Quint Winchester, aged 46 years.

SCHILLING.—On May 8th, very suddenly, at near Lowestoft, George Schilling, L.M.S.S. his 69th year.

WESLEY.—On May 6th, at Nottingham, Frank Willi O.B.E. (Mil.), M.D. Lond., late Act. Major, B.E.F., aged 65.

N.B.—A fee of 7s. 6d. is charged for the insertion of

ADDRESSES AND ORIGINAL ARTICLES

BIOCHEMICAL BASIS OF THYROID FUNCTION*

By C. R. Harington, M.A., Ph.D., F.R.S.
PROFESSOR OF PATHOLOGICAL CHEMISTRY IN THE UNIVERSITY OF LONDON AT UNIVERSITY COLLEGE HOSPITAL MEDICAL SCHOOL

I

It is scarcely possible to give a connected account of the present state of knowledge concerning the biochemistry of the thyroid gland without paying some attention to the historical development of the subject; since this development is not without its own intrinsic interest I shall devote a part of the first of my two lectures to a consideration of its more prominent features. Although, as will be seen, the problems connected with the thyroid which remain unsolved are numerous and important, the advance of knowledge even to its present stage affords a striking example of the manner in which independent lines of research by medical men, physiologists, and chemists may ultimately converge nd in so doing may contribute to the solution of a iological problem.

The lines of development which I should like to in outline are those of views on the function f the normal thyroid gland and of ideas which have een held concerning the abnormalities of the gland volved in endemic goitre and cretinism, diseases h until recent years have been of great tance.

Early Theories of Thyroid Function

he first anatomical description of the thyroid iven by Wharton in 1656 and the physical eristics of the organ suggested to this author possibilities as to its function. The most distinguishing feature of the thyroid is the e of the peculiar viscous fluid or colloid with the follicles of the gland are filled; this nce was regarded by Wharton as a lubricant trachea to which it was supposedly conveyed h special ducts. A second point which struck n was that the gland was generally of a larger women; in the female sex in particular he regarded it as fulfilling a cosmetic giving grace to the contour of the neck. r date observers became impressed with beral blood-supply of the *thyroid*, and of this led to a theory which held the e time—namely, that the thyroid acted r shunt and thus regulated the supply the brain. Here again the larger size in women was adduced in support of it, for Rush of New York wrote in provision was necessary to guard the from the influence of the more numerous tation and vexation of mind to which sed than the male sex." An amusing ingenious suggestion of Rush was made ter (1820). "If," he says, "it were that the thyroid contains more blood mes than at others, this effect would be the naked eye; in this case women would have long ceased to go about with bare husbands would have learnt to recognise the swelling of this gland as a danger signal of threatening trouble from their better halves."

From time to time other suggestions with regard to the thyroid were advanced, as for instance that it was the organ of sleep and that it was essential for normal voice production, but all these hypotheses fell to the ground sooner or later for lack of objective support, with the result that as lately as fifty years ago the general belief of physiologists was that the thyroid, in the adult at least, performed no essential function whatever. The evidence which was needed finally to change this conception and to lay the foundations of modern knowledge of the thyroid came not from the physiologists, but from the medical men who had to deal with pathological conditions of the gland.

Essential Nature of the Thyroid

Goitre as an endemic disease had been recognised from very early times; mention of it occurs in the writings of Pliny and it is discussed by all the mediæval medical writers. As the name indicates goitre was first regarded merely as a swelling of the throat, but when the thyroid became recognised it was realised that it was this organ which was specifically affected in the disease. It was also gradually realised that endemic goitre was intimately associated in some way with the form of congenital idiocy which was known as cretinism.

In districts where goitre was endemic a very large proportion of the population was affected; in these regions the swelling of the neck came to be regarded as the normal state of affairs, and indeed there exist accounts of communities where there was rivalry between the inhabitants in the matter of the size and shape of their goitres and where visitors with normal necks were looked upon with pity as being deficient in one of the natural adornments of the human body. Whatever the cosmetic value of a goitre might be, however, there was no doubt that if the swelling reached an excessive size considerable discomfort and injury to health ensued; therapeutic measures had therefore to be devised to deal with the condition. I shall have occasion later to refer to the early medical treatment of the disease; at the moment I am concerned with the development of the technique for surgical removal of the swelling.

The usual surgical practice was to remove a part only of the goitre, but in some cases, where the pressure symptoms were very severe, total goitrectomy was effected, and it is to the careful study of a series of such cases published by Kocher in 1883 that we owe the first proof that the thyroid is indeed an essential organ. Kocher observed that whilst total goitrectomy effected, as was to be expected, a marked immediate improvement in the condition of his patients, their subsequent history was unsatisfactory. Some months after the operation a definite set of pathological symptoms began to appear; the skin became dry and thickened, the hair began to fall out, and the mental processes grew dull; in Kocher's own words the patients became "cretinartig"; they appeared to be relapsing into a condition analogous with that of the congenital idiots already mentioned as occurring frequently in areas of endemic goitre.

About ten years earlier there had been described by Gull a curious condition in middle-aged women which was characterised by a set of symptoms very similar to those which appeared in Kocher's patients; this condition was named by Ord (1878) myxœdema

---

Oliver-Sharpey lectures for 1935, delivered before the llege of Physicians of London on March 26th and 28th. ct. will appear in a forthcoming issue.

and was definitely associated by him with atrophy of the thyroid gland. The brothers Reverdin (1883), who confirmed the observations of Kocher on the effects of total goitrectomy, noted the similarity of the post-operative condition of their patients with that of sufferers from myxœdema. It was also observed that removal of the thyroid from animals (especially young animals) produced certain changes which whilst not entirely similar to those present in human myxœdema were clearly analogous therewith.

The observations that the thyroid was an essential organ in man and animals and that its atrophy in the human being caused a definite disease led naturally to experiments on the treatment of this disease by a method of replacement. Schiff (1884) had obtained some evidence that the effects of thyroidectomy in animals could be relieved by grafting thyroid tissue and the first attempts to treat human myxœdema were made by this method (Bettencourt and Serrano, 1890); no permanent success was attained since the grafted tissue failed to establish itself, but the period during which it was being absorbed was characterised by relief of the symptoms. Making the logical deduction from this observation Murray in 1891 attempted to treat a myxœdematous patient with continued injections of a simple glycerol extract of sheep's thyroid and was immediately successful; shortly afterwards it was found that the thyroid could be given equally well by mouth and the replacement therapy of myxœdema thus became established on a firm basis.

The actual nature of the essential function of the thyroid was obscured for some time by the effects of removal of the parathyroid glands; these were not recognised at this date as independent entities and tetany resulting from their removal was often an accidental accompaniment of thyroidectomy, particularly in carnivorous animals. The success of the replacement therapy however at least provided the final proof that the thyroid exercised its function through the medium of an internal secretion.

Soon after replacement therapy had become established it was observed that administration of large amounts of thyroid resulted in great increase in nitrogenous excretion, whilst there was diminished nitrogenous excretion in myxœdema; it was further shown by Magnus Levy (1895, 1897) that the total gaseous exchange, which is an accurate index of the total metabolism, was increased in thyroid intoxication and diminished in myxœdema. It therefore became apparent that the principal function of the thyroid was to control the metabolic rate of the body as a whole, and this generalisation still covers all the diverse physiological effects of the thyroid which have since been described except those which affect its relationships with other organs of internal secretion.

Iodine Therapy in Simple Goitre

Endemic goitre was known from ancient times to be confined to certain regions—usually mountainous districts relatively far removed from the sea. As exploration was extended it was realised that the disease was world-wide in distribution, but the general impression of the sort of regions in which it was likely to occur remained unchanged. Although many bizarre theories were advanced from time to time regarding the ætiology of the disease, the prevailing view was that the cause lay in environmental factors and most probably in some abnormality of the water.

Apart from the surgical measures which have already been mentioned the principal method of treatment of goitre was by the administration of burnt sponge. The earliest reference to this treatment which I have been able to find occurs in the writings of Arnaldus Villanovanus (c. A.D. 1280); thereafter it recurs constantly in the works of the mediæval European physicians. Curiously enough no reference to the burnt sponge treatment appears in medical works in this country until quite recent times. The method was however practised in England in the form of the "Coventry treatment for bronchocœle," a secret remedy in the possession of a family of chemists at Coventry. After this remedy had long been a source of considerable profit to its proprietors, its nature was ultimately divulged to Dr. B. Wilmer, who published an account of it in 1779; its value was apparently accepted, since Wilmer's account appears almost verbatim in Black's "Medical Dictionary" (1800).

Now in 1812 iodine was discovered accidentally by the saltpetre manufacturer Courtois in the ash of burnt seaweed, and in the next year was identified as an element by Gay Lussac; a few years later it was isolated from the sponge (Fyfe, 1819). About this time there was working in Geneva, where endemic goitre was very severe, a physician by the name of Coindet. Having heard of the discovery of iodine and bearing in mind the traditional goitre remedy of sponge ash, Coindet, although in ignorance of the actual isolation of iodine from sponge, made the inspired guess that the newly discovered element might be the active principle of the traditional remedy.

The success which attended the first tests which Coindet (1820) made of his theory was dramatic; large goitres of long standing disappeared with incredible speed in response to administration of iodine, and the enthusiasm aroused by the success was such that people took to carrying little bottles of the magic element hung round their necks like charms. This excessive enthusiasm had a most unfortunate effect, for the incautious administration of too large amounts of iodine led in not a few cases to the production of a severe form of hyperthyroidism which was much more dangerous to the patient than the original goitre, and the iodine treatment thus fell into disrepute.

The early success however had left its mark and led logically to the development of the idea that endemic goitre might be due to environmental deficiency of the element, the administration of which had such a dramatic effect on the disease. About the middle of the last century an extensive investigation on these lines was undertaken in France by Chatin (1850–1860), who demonstrated quite clearly that a relationship did in fact exist between environmental deficiency of iodine (chiefly as indicated by the low iodine content of the water) and the occurrence of endemic goitre. Chatin's results were not accepted by the French Academy, and his work therefore failed to make much impression at the time; it has however been amply confirmed by subsequent investigations in different parts of the world, particularly by McClendon in America and by von Fellenberg in Switzerland, and in view of the technical difficulties under which he laboured it is deserving of the greatest credit.

Iodine in the Thyroid

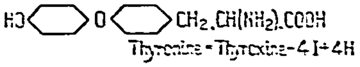
The connexion which various lines of works had clearly shown to exist between iodine and the normal functioning of the thyroid led that most able worker Kocher to postulate the existence of iodine in the gland itself, and it was at his suggestion that a search for iodine in the thyroid was instituted. This search was crowned with success in 1895 when Baumann demonstrated the presence of iodine in the ash resulting from alkaline incineration of a hydrolysis product of thyroid gland. Moreover, not only was Baumann able to show that iodine was present, but he found also that the amount of it bore some sort of relationship to the physiological activity of the gland as tested in replacement therapy; there was therefore a strong indication that the iodine actually belonged to the active principle.

It was soon found by Baumann that the iodine of the thyroid was practically confined to the colloid and that it was present in some sort of organic combination. From the colloid there could be prepared a characteristic protein, thyroglobulin (Oswald, 1901), which contained most of the iodine, and by gentle acid hydrolysis of this protein or of the crude colloid a certain concentration both of iodine and of physiological activity could be effected, products being obtained which under the best conditions contained 10–15 per cent. of iodine. No thorough purification could be effected by acid hydrolysis however, nor was enzymic digestion of thyroglobulin any more successful; the first real progress came when the method of alkaline hydrolysis was systematically studied. In 1914 Kendall succeeded, by hydrolysis of thyroid glands with 5 per cent. sodium hydroxide followed by a long and complicated process of fractionation, in isolating a minute yield of a crystalline compound containing 65 per cent. of iodine which he named thyroxine and which exhibited, qualitatively at least, all the physiological properties of the thyroid (Kendall, 1919).

Chemistry of Thyroxine

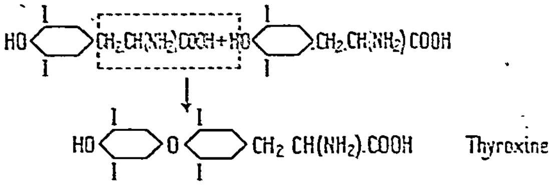
Progress with the chemistry of thyroxine was necessarily delayed until a more economical mode of isolation could be devised; this was eventually achieved in the form of a graduated hydrolysis with baryta (Harington, 1926[1]) by means of which there could be obtained from a good sample of dried thyroid somewhat over 0·1 per cent. of pure thyroxine. With the larger supplies of thyroxine which thus became available work on its constitution could be seriously undertaken. Removal of the iodine from thyroxine by a method which was known to involve no secondary alterations in the molecule gave a compound which was a phenolic amino-acid evidently related in some way to tyrosine. Systematic degradation of this product (thyronine) showed in fact that it was the *p*-hydroxyphenylether of tyrosine (Harington, 1926[2]). It is a matter of some interest that thyroxine is the first natural product in which the phenylether linkage has been found to occur (Fig. 1). Thyroxine was thus proved to be a tetra-iodo derivative of thyronine, but the positions occupied by the iodine atoms remained uncertain.

FIG. 1



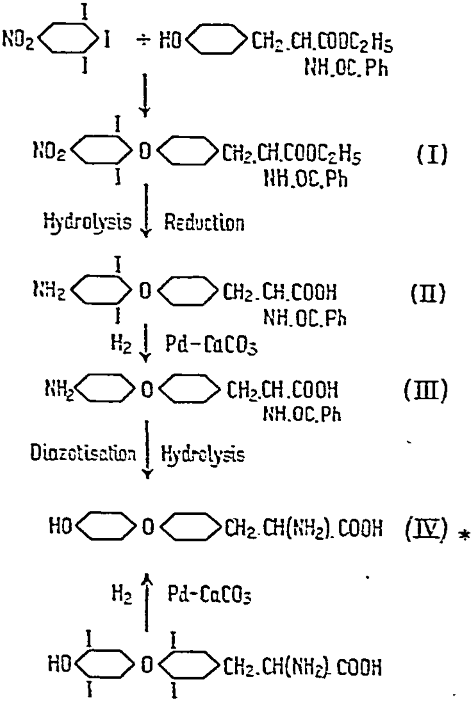
Now if we consider the possible ways in which thyroxine can arise in the body from known simpler precursors, we find that there is one course of reactions which is not only possible but highly probable. Until thyroxine was discovered only one other iodine-containing amino-acid was known; this was 3 : 5-diiodotyrosine, which had been isolated by Drechsel (1895) from a coral, and which is very readily produced from tyrosine in the laboratory by direct iodination of the latter in alkaline solution. (Incidentally it may be mentioned that 3 : 5-diiodotyrosine represents the form in which iodine occurs in the sponge.) We may assume therefore that interaction of iodine with tyrosine is likely to give rise to diiodotyrosine in the animal body. If such formation of diiodotyrosine is an intermediate step in the biological synthesis of thyroxine, the skeletal structure of the latter, as determined by the work on the constitution of thyronine, suggests that the final stage of the synthesis must consist of the coupling of two molecules of diiodotyrosine. There is only one way in which such a coupling is likely to occur—namely, by an oxidation involving the loss of the side-chain of one of the reacting molecules (Fig. 2).

FIG. 2



In this way we should obtain a compound in which the iodine atoms occupied the 3 : 5 : 3′ : 5′-positions of the molecule of thyronine. Certain features of its chemical behaviour also pointed to this constitution for thyroxine, but it was mainly upon the biochemical hypothesis that the attempt at the synthesis of thyroxine was based. The synthetic preparation of a compound of the suggested constitution did in fact yield a product which was chemically and physiologically indistinguishable from thyroxine isolated from the thyroid gland (Harington and Barger, 1927).

FIG. 3



* $[\alpha]_{5461}\left\{\begin{array}{l}+12{\cdot}2^{\circ} \text{ from tyrosine}\\ +13{\cdot}3^{\circ} \text{ from thyroxine}\end{array}\right.$

The successful outcome of this synthesis in itself provided confirmation of the biochemical theory upon which it was based. Further extensive support for this theory has since been provided by chemical and biochemical investigations. The biochemical facts in this connexion will be dealt with later;

at this point it is convenient to mention some recent work of a chemical character which has a direct bearing on the matter under discussion.

The case for the biological origin of thyroxine from tyrosine would obviously be greatly strengthened if the two naturally occurring compounds could be shown to be configuratively related. That they are *in fact so related* has been proved as follows (Canzanelli, Randall, and Harington, 1934). If *N*-benzoyl-*l*-tyrosine ethyl ester is condensed with 3 : 4 : 5-triiodonitrobenzene the compound (I) is obtained; on hydrolysis and reduction this is converted into the benzamido-acid (II) which in turn can be deiodinated to give (III) (Fig. 3). Diazotisation and hydrolysis of (III) then yield thyronine (IV). Since none of the reactions in the above synthesis involve the possibility of a Walden inversion the thyronine finally obtained must be related to the tyrosine employed as starting material. The thyronine obtained in this way from natural *l*-tyrosine had $[\alpha]_{5461} + 12{\cdot}2°$. A second preparation of thyronine was then made by catalytic deiodination of natural *l*-thyroxine, a process which again is known to involve no inversion; in this case the product had $[\alpha]_{5461} + 13{\cdot}3°$, and the configurative relationship between tyrosine and thyroxine was thus established.

At the stage which we have now reached therefore we may take it as established that the thyroid exercises its essential function as a regulator of metabolism through the medium of an internal secretion and that the characteristic physiological *properties of this secretion are concentrated in the* iodine-containing amino-acid thyroxine; moreover the latter compound originates in the body from tyrosine, the synthesis being effected through the intermediate stage of 3 : 5-diiodotyrosine. Discussion of the very important further question whether thyroxine constitutes the complete active secretion of the thyroid will be postponed until the second lecture, and the remainder of the present lecture will be devoted to consideration of the rôle of iodine in the ætiology of simple goitre.

Rôle of Iodine in the Ætiology of Simple Gotire

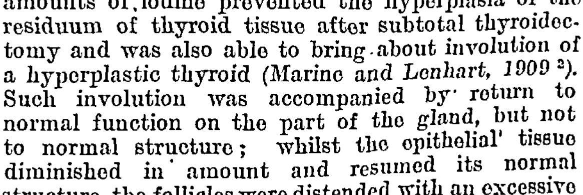
It was first shown by Halsted in 1896 that extirpation of a large proportion of the thyroid gland of a normal animal is followed by a characteristic overgrowth of the residual portion. This overgrowth consists of a change in character and an increase in amount of the glandular epithelium which lines the follicles of the gland. Normally the follicles are spheroidal and filled with colloid, whilst the lining epithelium consists of a single layer of flattened or cubical cells; during the process of hypertrophy which follows subtotal extirpation of the gland the cells of the epithelium become columnar in form whilst the colloid gradually disappears from the follicles; the latter thus lose their spheroidal form, being invaded by processes of the hyperplastic epithelial tissue, until ultimately the latter comes to constitute practically the whole of the gland. Having regard to the cause which elicits these changes they must be considered as being of a compensatory character—i.e., as representing an effort on the part of the small residue of gland to fulfil the function of the whole organ. Such an idea is evidently in accordance with the view that the colloid is the storage form of the thyroid secretion which is itself manufactured by the epithelial cells.

About ten years after Halsted's work appeared Marine began his extensive and fruitful observations on the spontaneously occurring enlargement of the thyroid which was common in man and the domestic animals in the region of endemic goitre where he was working (Cleveland, Ohio). Systematic examination was made of the thyroid glands of dogs (90 per cent. of which in this particular district showed more or less enlargement) and the work was subsequently extended to oxen, sheep, and pigs, and finally to man with similar results. It was found that among the glands thus examined all the stages of the characteristic glandular hyperplasia described by Halsted were represented; moreover it appeared that these changes could occur in two distinct series: (*a*) starting from a normal gland, and (*b*) starting from a colloid goitre (Marine and Lenhart, 1909[1]).

Now chemical investigation of these pathological thyroids revealed a most important fact—namely, that in those glands which exhibited more or less epithelial hyperplasia an inverse relationship existed between the iodine concentration and the total weight of the gland. In other words the more advanced was the hyperplasia the less iodine (and therefore presumably active secretion) did the gland contain. All thyroids which were histologically completely normal contained 0·1 per cent. or more of iodine calculated on the dry weight of the gland; with the appearance of early glandular hyperplasia the iodine concentration fell sharply below this critical level and as the pathological process progressed the iodine concentration ultimately became vanishingly small.

Marine's observations were next extended to the study of experimentally produced thyroid enlargement. He found that the same series of changes which had been produced by Halsted and which he himself was also able to elicit by partial extirpation of the gland, not only arose spontaneously in regions of endemic goitre, but could be brought about in the normal animal by restriction of the intake of iodine. On the other hand, administration of liberal amounts of iodine prevented the hyperplasia of the residuum of thyroid tissue after subtotal thyroidectomy and was also able to bring about involution of a hyperplastic thyroid (Marine and *Lenhart, 1909*[2]). Such involution was accompanied by return to normal function on the part of the gland, but not to normal structure; whilst the epithelial tissue diminished in amount and resumed its normal structure, the follicles were distended with an excessive amount of colloid and the result was in fact a colloid goitre. Reimposition of restriction of iodine intake caused such a colloid gland to undergo a series of changes precisely similar to those which have been described for the normal gland, and there thus emerges an experimental basis for the two series "normal" and "colloid" into which Marine divided his pathological material; the "normal" series representing the primary response of a normal gland to restriction of iodine, and the "colloid" series the response to the same stimulus of a gland which has already passed through the stages of hypertrophy-hyperplasia-involution one or more times.

Following Marine therefore we may recognise a cycle of changes through which the thyroid may pass as follows :—



noting that persistent restriction of iodine may break the cycle by preventing involution of the hyperplasia and causing fibrosis atrophy to supervene with production of myxœdema.

Consideration of the results of Marine's experimental work together with the facts which are now at our disposal regarding the nature of the active principle of the thyroid and regarding the relationship of environmental deficiency of iodine to the occurrence of endemic goitre seems to me to lead to a perfectly reasonable biochemical explanation of the ætiology of simple goitre. It is clear that restriction of the supply of iodine to the thyroid whether due to environmental deficiency of the element or to artificially imposed conditions produces the same effect on the gland as does subtotal extirpation; in the case of iodine starvation also therefore we must regard the reaction of the gland as compensatory in character.

In order that the metabolic processes of the body may be maintained at their normal level it is necessary that the thyroid should provide a certain minimum amount of its active secretion, for the manufacture of which a corresponding minimum amount of iodine must be supplied from exogenous sources. When a large proportion of the gland is removed, as in Halsted's experiments, we have seen that the residual portion responds to the increased demand upon it firstly by using up the colloid which represents its store of ready-made secretion, and secondly by hypertrophy of the glandular epithelium in the effort to increase the efficiency of its synthesising mechanism. It is not surprising that a precisely similar series of events should result from an additional strain imposed upon the gland by restriction of the supply of the essential precursor for manufacture of its secretion.

The conception that simple goitre represents a work-hypertrophy of the thyroid in response to restriction of the exogenous supply of iodine is adequate to account for almost all that is known of the occurrence of the disease in its endemic form. None of the many other theories which have been proposed from time to time to account for the malady have received any substantial support from observation or experiment, whilst, with the possible exception of certain areas in New Zealand, there is no region where goitre is severely endemic in which it has not also been possible to demonstrate an environmental deficiency of iodine.

It is evident that environmental deficiency of iodine alone cannot be made to account for all goitre. Goitre occurs sporadically in regions where there is abundance of iodine, and moreover goitre in man tends to exhibit certain peculiarities which are absent from the thyroid enlargements commonly observed in animals. Interference with the access of iodine to the thyroid may however occur in other ways than as the result of environmental deficiency of iodine, besides which it must not be forgotten that an additional demand for thyroid activity imposed at a time when the intake of iodine is just sufficient for normal requirements will cause a relative deficiency of iodine which is likely to elicit a hypertrophic response on the part of the thyroid.

An example of the first possibility is probably afforded by the goitrigenic effect of diets rich in fats. This phenomenon has long been recognised in a somewhat indefinite way and was demonstrated experimentally by Mellanby and Mellanby (1921) with puppies. The effect is produced particularly strongly by unsaturated fats, and it seems reasonable to suppose that these may interfere with the absorption of the iodine which is taken in with the food and thus prevent the thyroid from obtaining its necessary minimum of iodine, although there may be no environmental deficiency of the latter.

The second possibility—namely, the production of a relative deficiency of iodine owing to imposition of additional demands on the thyroid—is illustrated by the fluctuations in the size of the thyroid which occur in normal women at different stages of the sexual cycle and by the fact that in regions of endemic goitre the disease is particularly liable to manifest itself at times when there is heavy physiological demand upon the thyroid—e.g., at puberty or during pregnancy. In Marine's work also the effects of artificial restriction of iodine intake were much more severe when the restriction was imposed on a pregnant animal—i.e., when there were both relative and absolute deficiencies of iodine.

It seems to me therefore that it is safe to make the generalisation that the immediate cause of all simple goitre is failure of access of a sufficiency of iodine to the thyroid; in the case of endemic goitre this failure is to be ascribed directly to environmental deficiency of iodine; in the case of sporadic goitre either directly to interference with the absorption of iodine or indirectly to the production of a relative iodine deficiency by the imposition of a demand upon the thyroid which, with its available supplies of iodine, it is unable to satisfy. In any case it is certain that no goitrigenic influence is at present known which cannot be antagonised by the administration of extra iodine. An interesting case of a natural antagonism of this sort is afforded by the Eskimos. The Eskimo diet contains a preponderance of fat and in view of the experimental production of goitre in animals by such diets the prevalence of goitre among the Eskimos might be anticipated. In point of fact the disease is unknown among this race, the explanation being that their diet includes a large amount of cod-liver oil, which is rich in iodine.

What has been said concerning the ætiology of simple goitre can be applied also to the ætiology of cretinism which must be regarded as the extreme manifestation of the results of iodine deficiency. In its endemic form cretinism is associated only with the most severely endemic goitre, and it is doubtful whether true cretinism occurs outside these special environmental conditions. A congenital disease strictly analogous with human cretinism has not been produced experimentally in animals; the nearest approach to it has been observed in the puppies born of bitches which have been subjected to subtotal thyroidectomy and/or restriction of iodine during pregnancy; in these cases the thyroids of the new-born puppies show a high degree of hyperplasia. In human cretinism of the extreme type on the other hand the thyroid at birth has already passed beyond the stage of hyperplasia to that of fibrosis atrophy, so that the disease may fairly be described as pre-natal myxœdema. The fact that the thyroid of a cretin has already undergone irreversible pathological change during intra-uterine development is sufficient to explain the relative incurability of cretinism by replacement therapy as compared with the curability of myxœdema in adult life which involves no more than a retrogression of fully developed physiological functions.

The peculiarities which distinguish goitre in man from the corresponding disease in animals are the greater tendencies in man for the disease to terminate in atrophy of the thyroid with resulting myxœdema or cretinism and for the enlargement of the thyroid to occur in nodular masses (so-called adenomata) instead of in the regular manner observed in animals. For the first of these peculiarities there is, so far as

I am aware, no explanation available; it may be noted however that true myxœdema and cretinism seem to be peculiarly human diseases, since even total extirpation of the thyroid fails to reduce the lower animals to a condition entirely similar to that of a human being suffering from advanced myxœdema, nor, as we have seen, can experimental cretinism be readily produced. The tendency towards nodular enlargement of the human thyroid may perhaps be explained by the fact that owing to greater variations in the intake of iodine and to greater fluctuations in the physiological demand upon the gland, the human thyroid may be subjected to more frequent repetitions of the hypertrophy-hyperplasia-involution cycle; it has been shown by Womack and Cole (1931) that repeated induction of such series of changes by injection of irritant substances into the thyroids of animals may give rise in these also to nodular hypertrophy analogous with that found in the human subject.

However this may be, the final proof of the hypothesis of the association of iodine deficiency with endemic goitre is to be found in the success which in recent years has attended prophylactic iodine therapy. The original iodine therapy practised by Coindet and his followers failed because the dosage employed was excessive and because the curative treatment only was tried. Since it has been realised that iodine is of most effective use as a prophylactic and since biochemical work has given an indication of the amount of iodine which is actually required the position has entirely changed. Since the first successful large-scale experiment of Marine and Kimball (1917, 1920, 1921) some fifteen years ago the practice of iodine prophylaxis in regions where there is environmental deficiency of iodine, particularly in Switzerland and in the United States, has become continuously more firmly established, and there seems reason to hope that with the judicious pursuit of such measures endemic goitre and cretinism will ultimately cease to constitute serious problems.

STAPHYLOCOCCAL PNEUMONIA AMONG INFANTS IN A MATERNITY HOSPITAL

BY C. M. SMITH, M.D. Glasg., D.P.H.

DEPUTY COUNTY MEDICAL OFFICER, DURHAM; RECENTLY DIVISIONAL MEDICAL OFFICER, PUBLIC HEALTH DEPT., GLASGOW

AN outbreak of staphylococcal infections occurred in July, 1933, in a Glasgow maternity hospital of 25 beds. The outbreak was of a decidedly unusual character and presented several features which are not without importance from the standpoint of preventive medicine. It is with pleasure that I thank Dr. W. R. Wiseman, city bacteriologist, Dr. F. E. Reynolds, pathologist, Stobhill Hospital, Dr. R. Cruickshank, bacteriologist, Glasgow Royal Infirmary, and Dr. M. A. Urquhart, bacteriologist, Stobhill Hospital, for kind permission to make full use of the valuable reports which each of them furnished and for advice they have given in the preparation of this paper.

Description of the Outbreak

FOUR FATAL PNEUMONIA CASES

In July, 1933, four infants, who had all been born in the hospital, died after an illness of short duration, the cause of death being ascribed in each instance to pneumonia. The following statement shows the date of birth, date of sickening, &c.

Case.	Sex.	Date of birth.	Date of dismissal from hospital	Date of sickening.	Date of death.
		July	July	July	July
1	F.	1st	13th	13–14th	15th
2	M.	1st	14th	14–15th	17th
3	M.	4th	—	16th	18th
4	F.	5th	18th	18th	19th

In all four cases the birth was normal, and the infants were healthy during the first 12 days of life.

Cases 1, 2, and 4 were reported to have become ill within 24 hours of leaving hospital, although no abnormality was observed at the time of dismissal, and, in the remaining case, death took place in the institution. At autopsy of two of the cases (Nos. 3 and 4), performed by Dr. F. E. Reynolds, pulmonary consolidation confined to one lobe was found, together with signs of a general toxæmia, and, therefore, it was at first suspected that a pneumococcal infection of unusual virulence and infectivity was the ætiological factor. Accordingly, on the following days (July 21st and 22nd, 1933), material obtained from the posterior pharynx of 18 members of the nursing staff and three of the mothers, whose infants had died, was examined by Dr. R. Cruickshank. From eight of the nurses and from two of the mothers, Group IV. pneumococci were isolated, but in no instance was a pneumococcus of Types I., II., or III. recovered. Furthermore, pneumococcus was not found in cultures from nasal and from throat swabs of infants in the hospital; nor, as will appear later, was this organism cultivated from material obtained at autopsy of the two cases examined. Thus, at an early point in the investigation, evidence was available which excluded a pneumococcal infection as the cause of the deaths. A streptococcal infection, on the other hand, did not, on epidemiological grounds, appear likely to be the responsible agent, because among the mothers in the hospital there had been no recent cases of puerperal sepsis or other manifestations of streptococcal invasion. Members of the nursing staff also, who were carefully examined, appeared to be free from any septic foci.

The identity of the responsible infection became apparent when the bacteriological and histological findings in the two cases autopsied were correlated with the cultures obtained by swabbing the infants in the hospital.

The following are the reports on the two cases autopsied, together with brief clinical histories. The bacteriological results were confirmed by Dr. Cruickshank, who also performed mouse inoculation tests.

CASE 3.—This infant when two days old was thought to have a slight cold, as there was some nasal discharge and occasional cough. On July 16th, when 12 days old, he became seriously ill with frequent respiration, and on the following day he was found to be fevered; signs of pulmonary consolidation were detected and some blood-stained discharge from the mouth was noted. Death took place on the 18th.

Post-mortem examination revealed the presence of a copious exudate over the whole of the pleural surface of the left lung and adjacent parietes. There was consolidation of the lower lobe of the same lung but, so far as touch was concerned, no consolidation of the upper lobe. There were no pathological changes in the right lung. A number of large petechial hæmorrhages under the visceral pericardium, especially in the neighbourhood of the posterior auriculo-ventricular groove, were observed. There was general congestion of the organs.

On *histological examination* of sections of the left lower lobe, numerous irregular and closely approximated abscesses were seen. The pulmonary tissue intervening between these was intensely congested and the alveoli were filled with an exudate, which, in places, was largely fibrinous and, in other parts, hæmorrhagic. In the intervening tissue also were numerous colonies of staphylococci. The lining of the smaller bronchi had been almost completely desquamated and the lumen contained pus and blood. At one place an abscess was seen surrounding the bronchial wall, portions of which had become necrotic, permitting the eruption of pus into the lumen. In the left upper lobe microscopical preparations showed the fibrinopurulent layer on the surface of the organ to contain a considerable amount of blood. In the pulmonary substance catarrhal changes in the bronchi were marked and there was a small amount of fibrino-cellular exudate in the alveoli. The interstitial cells had proliferated and small areas of collapse were present. In both lobes blood-vessels were greatly congested.

The *bacteriological results* were as follows:—

Organ examined.	Direct culture.	Mouse inoculation test.
Lung ..	*Staphylococcus aureus.*	Mouse survived.
Spleen ..	do.	Mouse died. *S. aureus* recovered.
Liver ..	No growth.	Test not performed.
Heart ..	do.	Mouse survived.

Commentary.—"At the time of the autopsy the case was considered one of acute lobar pneumonia affecting the lower lobe, with consequent pleurisy of the whole of the left pleural cavity. The result of the bacteriological examination, however, showed that it was not an ordinary case of pneumonia, as the pulmonary infection was due to staphylococcus and not to pneumococcus. The result of the histological examination was in agreement, the left lower lobe containing numerous abscesses, microscopical in size. The tissue intervening between these abscesses was shown to be completely consolidated, and this explains why the macroscopical appearances simulated those of acute lobar pneumonia due to pneumococcus. The case further resembled an ordinary acute lobar pneumonia in that the infection was confined to one, namely, the left lower, lobe. No precise reason could be offered to explain why the upper lobe of this lung or the right lung had not been infected."

CASE 4.—This infant made satisfactory progress after birth, and when taken from hospital at 10 A.M. on July 18th she appeared to be quite well. At 3 P.M. the same day, however, respiratory embarrassment was noticed; three hours later a little blood was coughed up, followed, it was reported, by vomiting of blood. Two practitioners who were called in diagnosed pneumonia. At 10 P.M. the same evening blood appeared from the nose, and during the night difficulty in breathing increased until death took place at 4 A.M. on July 19th. The duration of illness, from 3 P.M. on July 18th to 4 A.M. on the following day, was thus only about 13 hours.

At *autopsy* the right pleural cavity was found to contain a large amount of blood, and in the pericardial sac there was a small quantity of blood-stained fluid. The right lower lobe was completely consolidated, the lobe being reddish-purple in colour, but on macroscopical examination no consolidation of the other lobes was found. The heart-muscle was dark in colour and one or two small petechial hæmorrhages were seen under the visceral pericardium. Marked congestion of all the organs, especially the liver, was present. The stomach contained blood.

On *histological examination*, sections of the right lower lobe showed large portions to be consolidated owing to the alveoli being completely filled with blood. In the hæmorrhages numerous colonies of staphylococci were present, and, here and there, abscess formation was commencing. In the right upper lobe the lining of the bronchi had been desquamated to a great extent and the lumen contained the desquamated cells with a few red blood corpuscles. The histological picture of this lobe was exactly similar to that of the left upper lobe in Case 3 in that proliferation of interstitial cells had occurred with small areas of collapse: in parts a certain amount of hæmorrhage had occurred into the alveoli and small colonies of staphylococci were encountered.

The *bacteriological results* were as follows:—

Organs examined.	Direct culture	Mouse inoculation test.
Lung ..	Coliform bacilli.	Mouse died. *S. aureus* recovered.
Spleen ..	No growth.	Test not performed.
Liver ..	*S. aureus.*	Mouse died. *S. aureus* recovered.
Heart ..	No growth.	Mouse survived.

Commentary.—"The case was one of intense hæmorrhagic inflammation of the lower lobe of the right lung due to *S. aureus*, with the usual signs of general toxæmia. The blood in the stomach was due, probably, to swallowing hæmorrhagic exudate which had occurred into the right lung and had been coughed up."

The above results showed that in each case death had been due to *S. aureus* infection. A striking feature of both cases was that on naked-eye examination the pulmonary consolidation was confined to a single lobe.

With regard to Cases 1 and 2, in which no opportunity for a post-mortem examination was presented, it may be stated that in the former hæmorrhages were reported just before the end, and in the latter there were convulsions on the day of death. As these infants became ill at the same time as the cases investigated by autopsy, and, as the clinical history was similar, it is a reasonable presumption, amounting almost to a certainty, that they also succumbed to a staphylococcal infection of the lungs.

RESULTS OF NASAL AND THROAT SWABS OF INFANTS IN THE HOSPITAL AND COMPARISON WITH CONTROL GROUP OF INFANTS

The bacteriological and histological findings just described form an interesting comparison with the results of nasal and throat swabs of the infants in the hospital. The bacteriological work involved in the examination of these swabs and of swabs taken from a control group of infants in another hospital was done by Dr. Wiseman, who took a special interest in the outbreak. On July 20th, 6 infants, who were then in isolation on account of slight nasal discharge or occasional cough, were swabbed. Cultures from the nasal swabs yielded profuse growths of *S. aureus* in all cases, an unexpected and very arresting feature of the preparations. In 4, pure cultures were obtained, and in 2, streptococci were also present. With reference to the throat swabs, *S. aureus* was cultured in three cases, in each of which it was accompanied by streptococci: streptococci alone were found in two, and in the sixth case *Staphylococcus albus* and streptococci. Pneumococcus was not found in any specimen.

On July 26th, 15 infants, who were not in isolation and whose ages on that day ranged from three to ten days, with an average of 6·3 days, were examined. *S. aureus* was recovered from either nose or throat in all but 3. Nasal swabs gave profuse and vigorous growths of *S. aureus* in 12 cases, of which 10 were pure cultures, and in the remaining 2 cases streptococci were also found. Throat swabs yielded cultures of *S. aureus* in 9 cases: in only one instance, however, was a pure growth obtained, while in 7 streptococci were also present and in one case *Staphylococcus albus*. The organism, as cultivated from the nose in this group of 15 children, was much more vigorous in proliferation than that from the throat. These findings, especially the results of the nasal swabs, were considered by Dr. Wiseman to be most unusual and to indicate a widespread *S. aureus* carrier condition among the infants.

As a control, swabs were taken from a group of 16 healthy infants in another hospital on August 2nd, on which day the ages of this group ranged from 3 to 18 days, with an average of 7·7 days. Six of the nasal swabs yielded *S. aureus* and in two of these cases the same coccus was also isolated from the throat. In two cases *S. aureus* was cultured from the throat only. In each instance it was observed that the growths were scanty and that *S. albus* was also present. Cultures from eight of the infants were negative for *S. aureus*. The control group of children and the infants in the infected hospital were accordingly found as groups to exhibit marked differences in the bacteriological picture as far as concerned the numbers of *S. aureus* present. As it was evident that practically all the infants in the institution were harbouring *S. aureus*, it was recommended that further admissions should cease, and on the advice of a rhinologist a nasal ointment (2 per cent. argyrol) was employed in an effort to control the carrier condition. Fortunately no further cases occurred. By August 7th the last patient had left the hospital and on opening five days later, after disinfection had been carried out, there was no recurrence of the infection.

COURSE OF EVENTS IN THE HOSPITAL PRECEDING THE PNEUMONIA CASES

The exact source of infection in this outbreak was not discovered, but the course of events was ascertained to have been as follows:—

(1) On June 22nd, 1933, an infant in the hospital, then seven days old, was noticed to have developed sepsis of the subcutaneous tissues of the shoulder, which, in spite of surgical treatment, rapidly extended and was followed by widespread sloughing and undermining of the skin. The infant died in the hospital on June 30th. No examination of the pus was made until a few hours before death, when a swab was taken from a deeply seated pocket of pus. *Bacillus coli* and a late lactose-fermenting organism were isolated but these were probably secondary invaders.

(2) On July 2nd one of the mothers in the hospital and on July 6th two of the mothers began to suffer from mastitis. Incision of the abscess was done in all three cases between the 5th and 11th, and in no instance was the pus examined. A feature of these cases, of which the significance could not be tested, was that immediately prior to the development of mastitis they were all attended by the same nurse, who, unfortunately, had left the institution before inquiries were made.

(3) Between July 1st and 16th, and especially during the first five days of the month, an unusual prevalence of minor septic skin lesions was recorded. On an average three to four children required attention for septic spots, although on one day as many as nine infants were noted as having been treated.

(4) On July 12th an infant, who was then six days old, developed a breast abscess which required incision two days later. The infant was isolated in the hospital from the beginning of the disease. No bacteriological examination of the pus was made.

(5) Between July 13th and 29th 11 infants were isolated in the hospital for periods varying from three to six days on account of mild catarrh of the upper respiratory tract.

It was between July 13th and 18th that four infants sickened and died after an illness of less than 48 hours' duration from what was clinically regarded as pneumonia. In two of the cases death was proved at autopsy to have been due to *Staphylococcus aureus* pneumonia.

It may also be noted that among the 55 mothers who were dismissed from the hospital between July 1st and August 7th, and who resided in Glasgow, 6 cases of suppurative mastitis were subsequently found on a follow-up inquiry. If the 3 cases of breast abscess which occurred in the institution between July 2nd and 6th are included, this means that there were in all 9 instances of mammary infection among the adult patients. Of the 6 cases in which mastitis appeared subsequent to dismissal there were 2 which are worthy of note. The mother of infant No. 4, who died of staphylococcal pneumonia on July 19th, was dismissed from hospital on July 18th, and ten days later she contracted a mammary gland infection which required incision. The other case was the mother of the infant who, as noted above, was found on July 12th to be suffering from a breast abscess. This mother left hospital before her child and returned twice daily to nurse her baby until his dismissal on July 26th. On the 28th a breast abscess developed in the mother which had to be incised about a week later.

It is necessary to mention what is regarded as an important factor in the spread of infection once this had gained entrance. The infants normally slept at night in cots in the ward beside their mothers. If, however, a child should be noisy he would be removed to a large room, which was the infants' bathroom but was also known as the night nursery. This room, incidentally, was deficient in light and ventilation, and after the epidemic the defects were remedied by structural alterations. In the early part of July, 1933, an unusual number of children had to be taken to the nursery on account of being restless at night, and on one occasion as many as 18 infants slept there. The nursery contained two barrows for holding infants; one, 7 ft. long with eight compartments, and the other, 4 ft. long with five compartments. When the barrows were fully occupied there was thus a distance between heads of infants of 10½ in. in the former and 9¾ in. in the latter. It is obvious that once an infection had obtained a footing, sleeping arrangements provided by barrows of this nature would readily facilitate the spread of disease. Such barrows should probably not be used at all, and if in institutions they are found indispensable, then they should be reserved for purposes of transport and other functions of a temporary nature.

Discussion

In the absence of bacteriological examination of pus from the case of phlegmonous abscess, from the cases of mastitis, and from the cases with septic spots, there is no indisputable evidence that the series of events narrated is not simply a collection of chance happenings. The first case with the phlegmonous subcutaneous sepsis may have been due to a staphylococcal or to a streptococcal infection; there is agreement, however, that in superficial septic skin lesions and, more particularly, in mastitis the staphylococcus is the organism most frequently recovered. Since two of the fatal cases were proved to have succumbed to a staphylococcal pneumonia, and the other two similar cases not autopsied were almost certainly due to the same infection, and since examination of the infants, some of whom were suffering from symptoms of upper respiratory-tract catarrh, showed that they were practically all harbouring *S. aureus* in the nasal and faucial passages to a very unusual degree, it is justifiable to conclude that, with the possible exception of the first case, the various events are all closely related ætiologically. In other words, all the cases are considered to be different clinical manifestations of the same infection and to form one epidemiological event.

In outbreaks of a streptococcal origin varying clinical representations are not uncommonly encountered—e.g., tonsillitis, scarlet fever, otitis media, puerperal sepsis, erysipelas, and pneumonia—but in an outbreak of staphylococcal causation a similar phenomenon is unusual. In ordinary circumstances *S. aureus* is thought not to possess the same degree of infectivity as that of the streptococcus. Attention is drawn to the fact that no serious case of illness occurred among the mothers and that the terminal phase of the outbreak consisted of four cases of fatal pneumonia. The latter fact supports the statement of Menten and others (1932) that "*Staphylococcus aureus* seems to have the propensity for inducing disease in infants that is not so evident in older persons." It is also remarkable that among the infants who suffered from minor septic skin lesions, no case of pemphigus neonatorum occurred. Swendson and Lee (1931) state that numerous observers have confirmed the fact that the responsible organism in this infection is a specific strain of *S. aureus*.

With regard to staphylococcal pneumonia, the disease is not uncommon and is generally secondary either to a septic focus elsewhere in the body or to an acute infection such as influenza, measles, or whooping-cough.

Chickering and Park (1919) in an investigation of 312 deaths from influenzal pneumonia found 135 to be associated with *S. aureus* in the lung. These cases were considered to possess characteristic clinical manifestations.

Menten and others in a bacteriological study at necropsy of 131 cases of pneumonia in children, both primary and terminal, isolated the staphylococcus alone in 11 instances and mixed with other bacteria in 65 cases.

Reimann (1933), after quoting a number of investigations, states that the incidence of staphylococcus lung infection has not changed materially since Netter's report of 1892, in which he found the staphylococcus in pure culture in 7·7 per cent. of his cases. Reimann describes 6 cases of what is regarded as primary staphylococcal pneumonia; in all his cases there were preceding conditions—viz., influenza-like infection (2 cases), asthmatic bronchitis, sore-throat, chronic nephritis, and malnutrition.

I have found no record of any outbreak of staphylococcal infection, including cases of pneumonia in infants.

It will appear from the facts recorded here that serious risks may be involved in any institution where infants are tended if lesions due to *S. aureus* are not regarded as of potentially serious import.

Summary

Four infants born in July, 1933, in a maternity hospital died of pneumonia within four days of each other. Three of the children became ill within 24 hours of leaving the institution, although no abnormality was observed at the time of dismissal, and the other one died in the hospital. The duration of illness in each case was about two days. At autopsy, which was held in two cases, the cause of death was shown to be staphylococcal pneumonia, and a feature of the pathological findings was that in both instances consolidation was on macroscopical examination confined to a single lobe, thus simulating acute lobar pneumonia. From swabs taken from infants in the hospital, six of whom were suffering from catarrhal symptoms, profuse growths of *Staphylococcus aureus* were recovered from the nasal and faucial passages in practically all cases. Examination of a control group of infants in another institution demonstrated the unusual incidence of the staphylococcus infection among the children in the infected hospital. It was ascertained that within the previous fortnight an infant had died of a phlegmonous abscess, three mothers and an infant had suffered from suppurative mastitis, and that among the infants there had been an unusual prevalence of minor septic skin lesions followed by a number of cases of mild upper respiratory catarrh. Further, 6 cases of mastitis after dismissal were discovered among 55 mothers who left the hospital between July 1st and August 7th. With the possible exception of the phlegmonous abscess, all the foregoing cases, including the 4 fatal pneumonia cases, are considered to have been different manifestations of staphylococcal infection and to form one epidemiological group. The spread of the disease was possibly facilitated by the nature of the temporary sleeping arrangements provided for the infants.

RECENT OBSERVATIONS ON PSITTACOSIS

BY WALTER LEVINTHAL, M.D. Munich

(From the National Institute for Medical Research, Hampstead)

DURING last year psittacosis, or parrot disease, has again attracted wide attention and the memory of the pandemic of 1929–30 has been revived. K. F. Meyer and B. Eddie have reported the widespread infection of Californian aviaries and breeding farms, and many human cases have occurred in Holland and especially in Germany. According to the figures of J. Fortner and R. Pfaffenberg, the number of human cases in Germany was nearly 150 during the first six months of 1934, that is almost three-quarters of the total number in 1930. The recent disease has generally appeared in the form of family endemics, and the investigations have revealed, with rare exceptions, the remarkable fact that the source of the infections was not a sick parrot, but an apparently healthy budgerigar. In Germany, as in most European countries, the commercial importation of parrots and parakeets has been prohibited since 1930. This has prevented the importation of the disease from overseas, but the widespread dissemination of the psittacosis virus in 1930 evidently infected the domestic stocks, and the home-bred parakeet has become the conveyor of the disease to human beings. The budgerigar is less susceptible to psittacosis than are most species of parrots, and frequently becomes an apparently healthy carrier of the virus. This fact was proved beyond doubt for the first time in 1931, at the Robert Koch Institut in Berlin, where I was in charge of the psittacosis investigations in Prussia. The case was reported by the president of the Reichsgesundheitsamt, at the Office Internationale d'Hygiène Publique, Paris, in October, 1931, and April, 1932. The history of the case was as follows:—

In April, 1931, a family in Cologne, consisting of husband, wife, and stepson, fell ill with typical psittacosis which ended fatally in one case. Four apparently healthy budgerigars were found by the inspecting veterinary officer in the home of the patients. The birds were killed and sent to Berlin. To save experimental animals I pooled the suspensions of the organs (heart, spleen, liver, and lungs) of all the birds and diagnosed the presence of the virus by transmission to some canaries, all of which died of psittacosis.

The recent increase of psittacosis in certain places suggests that latent infection may also exist among budgerigars in this country. Obviously such an infection would remain unnoticed, even unsuspected, so long as no human cases attracted attention. Even the development of the disease and occasional deaths from psittacosis among the birds might escape observation. The epidemic of 1930 was widespread in England and it would be astonishing if no nidus existed.

The existence of such a nidus has been proved conclusively by certain work carried out at the National Institute for Medical Research during 1934. Through the kindness of the Ministry of Health I received on May 22nd last a budgerigar which had died four days previously. The bird was home-bred at an aviary in the South of England. The heavy contamination of the internal organs with a spore-bearing bacillus necessitated the filtration of the material. Mice were inoculated intraperitoneally with the filtered suspension of spleen and liver and died on the fifteenth and eighteenth days of typical psittacosis. A few weeks later two further birds, a rosella parakeet and a budgerigar from the same source, succumbed to psittacosis. In these two latter cases the diagnosis was made, not only by transmission to mice, but also by the direct microscopical demonstration of the virus in the typically affected organs of the birds. At the same time I was able to find psittacosis in three budgerigars which died in a large private aviary, in two of them immediately, by the miscroscopical demonstration of the virus. In this latter instance the infection was not due to an existing nidus but to a fresh importation. The history of that importation reveals a new fact.

On April 27th last a consignment of about 500 red cockatoos (galahs) and budgerigars arrived at Plymouth direct from Adelaide in Australia. The birds were intended for Belfast, but were collected provisionally by a dealer in London. It is believed that there had been a number of casualties among the birds during the voyage. Very shortly after their arrival here 8 galahs and 6 budgerigars died from psittacosis. The virus was demonstrated by transmission to mice, and in 5 of the birds—for the first time in naturally diseased parrots—directly by microscopical examination. The remainder of the Australian consignment had already been shipped to Belfast, where the infection continued, as the examination of 5 further dead galahs proved, so that the whole consignment, fortunately quarantined after warning by the English authorities, had to be destroyed. A second cargo of 52 budgerigars and 90 cockatoos from Australia, already at sea when the infection of the first was diagnosed, arrived a month later. Afterwards it became known that 43 of the birds had died during the voyage. Some of the birds immediately after arrival had been distributed to well-known aviculturists in this country. One of the fanciers, who had been warned after receipt of the birds, was the owner of the private aviary mentioned above, where the infection continued for some time.[*]

The fact that psittacosis, which previously was believed to occur naturally only in South America, is endemic also among Australian parrots and parakeets was unknown hitherto. A little later Meyer and Eddie reported the demonstration of the virus in budgerigars trapped in the vicinity of Adelaide. On their arrival in California the birds appeared perfectly healthy. They were strictly isolated, yet one month after their arrival cases of psittacosis occurred among them.

Quite recently, after the official communication of my results to the Australian authorities, infection has been proved in that country by F. M. Burnet (Med. Jour. of Australia, 1934, ii., 743.) Healthy parrots and parakeets, purchased at random from different dealers in Adelaide and Melbourne, were examined. Of 24 birds in Adelaide 33 per cent. were detected as carriers of the virus in the enlarged spleen. In Melbourne 9 or 10 out of 12 grass parakeets were probably carriers.

The freshly isolated strains, together with an old strain which I owe to the kindness of Prof. S. P. Bedson, presented the desired opportunity for me to continue at the National Institute for Medical Research my studies of the psittacosis virus, which were started in the beginning of 1930 at the Robert Koch Institut in Berlin. Some of the results of these previous and recent investigations may be mentioned here.

PSITTACOSIS IN THE MOUSE

The research on the disease in many laboratories during the pandemic of 1930 has afforded two facts of paramount importance for the diagnosis of psittacosis: the discovery of the virus and the recognition of the white mouse as a suitable experimental animal. The latter fact, established first by C. Krumwiede and co-workers in 1930, and studied thoroughly by T. M. Rivers and G. P. Berry, has made the laboratory work with psittacosis much less dangerous than when parrots, canaries, or rice birds were used (F. Neufeld and Levinthal). Nevertheless, the utmost caution must be observed, and this has been emphasised by some recent laboratory infections in Germany, one of which ended fatally. The experimental disease in the mouse is very characteristic. According to the amount of the virus injected intraperitoneally, the animals succumb after from two to thirty days. The symptoms of the illness, which may last for a period of one to several days before death occurs, consist of ruffled fur, eyes closed, often with some discharge, apathy, sometimes, but not often, diarrhœa.

---

[*] On April 20th, 1935, a consignment of parrots was imported from Australia by special permit for avicultural purposes. Most of them died on the voyage. Examination of a number of birds which died after arrival here revealed again the presence of the psittacosis virus.

The conditions found on post-mortem examination show three main types:—

(1) *Death 2–5 days after infection.*—The peritoneum contains a little sticky and stringy fluid, the liver is yellowish-pale and mottled, the spleen is of normal size and bright red, sometimes full of yellowish spots. The pericardial fluid is somewhat increased. Microscopically the liver and the spleen show small hæmorrhages and necrotic areas. The virus is abundantly present in the cells of the peritoneal fluid, of the omentum between stomach and spleen, and especially in the spleen, but is found in smaller amounts in the liver and the pericardium, but not in the pericardial fluid. The focus of infection is the reticulo-endothelial system, the cells of which are packed with the germs and show karyopyknosis and vacuolisation and fatty degeneration of the cytoplasm.

(2) *Death 5–15 days after infection.*—The abdominal cavity is filled with thick fibrinous masses, the intestines stick together, liver and spleen are coated with thick fibrinous membranes, which can be easily stripped off and cover a perihepatitis and perisplenitis. The fluid in the pleural and pericardial cavities is increased and clouded by fibrin and endothelial cells. The virus is present abundantly in the peritoneal exudate, especially in the perihepatitic and perisplenitic membranes, and in the cells of the pericardial fluid and in the pericardium itself. It is scarcer in the spleen.

(3) *Death 15–30 days after infection.*—The abdomen is distended, sometimes enormously, by a cloudy ascitic fluid, the pleural and pericardial cavities are filled with a serous-fibrinous exudate. Liver and spleen may be enlarged and friable. Serositis dominates the syndrome. The virus is extremely scarce in the ascitic exudate and in the spleen. The most suitable material for its demonstration is the pericardium.

In all three types the blood of the mouse contains very little virus, which is only to be seen occasionally in an endothelial cell. This is in striking contrast to its abundance in the blood of naturally or experimentally infected birds, where many desquamated endothelial cells are packed with it, or large clusters and groups of the virus are to be seen in the fluid when the cells have broken down.

As in the human patient, *pneumonia* is not a regular symptom of the disease in the experimental animal.

In the intraperitoneally infected mouse a lung affection is only observed occasionally. In early stages circumscribed red spots which resemble infarcts are found; microscopically these spots, and sometimes larger areas, consist chiefly of hæmorrhages into the alveolar walls, which compress the alveoli. In later stages an entire lobe or even one complete side may be transformed into a dark red, liver-like organ which suggests a genuine pneumonia; but the microscopical examination reveals that the alteration represents a collapse of the empty alveoli caused by hæmorrhages and œdema with accumulation of cells in the alveolar walls. Apparently this lung condition arises from the blood-vessels, where the virus attacks and destroys the endothelial cells.

To sum up, the essential characteristic of psittacosis is the infection and the destruction of the reticulo-endothelial system.

THE CAUSAL AGENT

The ætiological agent of the disease is a filter passer, as Bedson, Western, and Simpson reported first in January, 1930, and as many investigators confirmed at the very beginning of their researches during the pandemic of 1930. Thus the former "bacillus psittacosis" of Nocard (1892) and the different bacteria more recently described as the causal agent may be discarded definitely as ætiological factors. Very soon, however, it became evident that the filtrability of the psittacosis virus is rather limited. Only the more porous types of filter candles such as Chamberland L2 and Berkefeld V allow the virus to pass. In complete agreement with these filtration experiments are the observations with centrifugation; even a short spinning at relatively low speed diminishes appreciably the degree of infectivity of the supernatant fluid (Levinthal), and a high-speed centrifugation for a prolonged time deprives the supernatant fluid almost completely of the virus, which is concentrated in the deposit (Bedson and Western). Both the results of filtration through filter candles and of centrifugation indicated that the virus is of considerable size. At the National Institute for Medical Research I found an excellent opportunity to define more exactly the minimum size of the virus particles. Mr. Elford kindly placed his filtration arrangements at my disposal. By means of his carefully calibrated "gradocol" membranes the minimum size of the psittacosis virus was determined as 0·22–0·33 μ.

This result proves that the causal agent of psittacosis must be within the limit of microscopical resolution. Indeed, it corresponds exactly to the microscopical observations which were first published in the spring of 1930, and have been confirmed since then by nearly all investigators who have studied the disease. At a meeting of the Berliner Microbiologische Gesellschaft on March 24th, 1930, I reported the discovery of minute coccoid bodies in exudates and in certain infected organs, and described shortly afterwards the extraordinary pleomorphism of the germ, which strikingly resembles that of *B. tularense*. R. D. Lillie (April 11th, 1930) described the same structures and compared them with rickettsia. A. C. Coles (THE LANCET, 1930, i., 1011) was the first to report the same micro-organisms in blood-films of human cases. Bedson and J. O. W. Bland thoroughly studied during the following years the development of the micro-organisms and favoured for a period the hypothesis, that this virus is not a bacterium, but possesses protozoal affinities with a developmental cycle of amœboid forms or plasmodium, morula, division and subdivision of elements of morula, elementary bodies; but recently they have withdrawn this hypothesis and agree with the opinion that this virus is a micro-organism with bacterial affinities.

The general confirmation of the findings and the satisfaction of nearly all investigators as to the nature of the bodies leaves scarcely room for any doubt about the ætiological significance of the structures. Nevertheless, I endeavoured to make the final conclusive step according to the postulates of Henle and Robert Koch, that is, to obtain a pure culture capable of subculture in any series and to test the virulence of the cultivated virus. The first success in obtaining multiplication in an artificial medium (modified Maitland medium) was reported in 1930 at the 1st International Microbiological Congress (Levinthal). Since 1932 Bedson and Bland have studied the growing of the virus bodies in explanted pieces of mouse spleen and chicken embryo. Since January, 1934, I have been able to cultivate several strains† in a medium, similar to the medium of C. P. Li and Rivers for the cultivation of vaccinia and louping ill virus.

A small amount of thoroughly minced tissue of a 9 to 11 days old chicken embryo is suspended in 5 c.cm. tyrode solution in Carrel flasks. This medium yields an abundant growth after incubation for 3–4 days after inoculation, and this is easily subcultured by the transference of one drop of the ground-up tissue particles to freshly prepared flasks. Any of these well-grown cultures, if tested on the mouse, shows an undiminished virulence of the virus—

---

† Mentioned in the report of the Medical Research Council for the year 1933–34. January, 1935, p. 38.

that is, an infectivity still in dilutions of 10^{-8}. Moreover, the cultures offer an excellent material for watching the development of the micro-organisms during the different periods of cultivation by means of suitably prepared and stained specimens, which reveal again the remarkable pleomorphism of the virus.

The multiplication occurs exclusively in the surviving tissue, preferably within the endothelial and epithelial cells; only after the breaking up of the degenerating cells do the virus bodies become free and appear in the fluid. In a freshly prepared medium the virus is mainly found in the form of deeply staining cell inclusions varying much in size and shape, which, if broken up by force during the preparation, crumble to irregular pieces. These inclusions are similar in nature to the cytoplasmic inclusion bodies of other virus diseases, but with the difference that the matrix of the inclusion body is basophilic, as Bedson and Bland rightly emphasise. Later on these inclusion bodies are more and more replaced by intracellular colonies of all sizes, composed of the distinct and separate minute virus bodies. These two extremes, and all kinds of intermediate forms, are to be seen often enough at the same time.

It seems to me evident that this pleomorphism depends upon the environmental factors. When the virus invades a healthy, vigorous cell, an immediate multiplication is hampered by unknown factors. The virus passes through a latent period, during which division is checked. The virus particles swell up and form a mass embedded in a deeply stainable matrix, which obscures all detail. This enlargement may be due to the accumulation of nutriment in the virus particles. The result is a typical inclusion body. Later, when the host-cell weakens more and more as shown by the progressive vacuolisation of the cytoplasm and the karyopyknosis, unbounded growth of the virus is able to take place. Division then commences and an intercellular colony is formed, composed of distinct elements, which become more and more uniform and minute, until the whole of the cell is packed with these bodies and finally bursts.

When on the other hand the virus encounters a considerably damaged cell, a prompt and unchecked multiplication leads to the immediate formation of such colonies, which, from the initial stage, are composed of the minute and distinct elements. As an intermediate stage there occur small colonies composed of distinct cocci and diplococci nearly as large as staphylococci, but without any matrix.

In my opinion these larger forms are not a regular initial stage of the virus, as Bedson and Bland still believe. They are forms, developing whenever the ratio between nutrition and multiplication is temporarily disturbed. Moreover, if this virus is indeed a minute bacterium, multiplying by simple division, there cannot exist an "initial" stage and the words young or old lose any significance.

Finally, still another morphological group has to be mentioned, more conspicuous in infected animals than in cultures. This is obviously an involution or degenerative form, swollen up and pale, appearing sometimes as rings, sometimes as large discs, sometimes as barrel-shaped rods with bipolar staining, resembling very thick pasteurellæ.

The demonstration of this organism in any one of its typical forms must be the conclusive point in every definite diagnosis of the disease. The multiformity of the psittacosis virus seems to me the most characteristic feature of the microbe. The cultivation and the reproduction of the disease by the pure culture prove beyond doubt the ætiological significance of the micro-organism. The behaviour of the virus in the preparations of infected organs and the observation of the growing culture, together with the filtration experiments, reveal the characteristic attributes of a minute bacterium. All these facts warrant the name I have given to the microbe and published in 1930: *Microbacterium multiforme psittacosis*.

In addition, it may be mentioned briefly that I have attempted to immunise mice by active vaccination. The vaccines were prepared in various ways and injected intraperitoneally several times. The addition of a small amount of formalin or the photodynamic inactivation of the virus by the method of Perdrau and Todd with methylene-blue and radiation proved to be very effective. The treated mice became immune against a ten-million-fold lethal dose of the virus.

This work has been carried out under a grant of the Rockefeller Foundation. I wish to express my thanks to the Medical Research Council and Sir Henry Dale, F.R.S., for the opportunity of continuing my researches at the National Institute. My thanks are also due to Captain S. R. Douglas, F.R.S., Mr. W. J. Elford, Ph.D., and to the medical staff of the Ministry of Health.

CARDIAC MENSURATION

By Franklin G. Wood, M.B. Camb., D.M.R.E.

RADIOLOGIST TO THE CITY OF LONDON HOSPITAL FOR DISEASES OF THE HEART AND LUNGS, VICTORIA PARK, AND TO THE GERMAN HOSPITAL, LONDON

There is no need to-day to stress the importance of radiology in the diagnosis of pulmonary disease. Chest radiograms have reached a perfection scarcely dreamed of ten or fifteen years ago, when all the radiologist could do after studying a thoracic plate was to hazard a guess as to the presence or absence of gross disease. But it must be confessed that the investigation of the heart by radiological means has not reached an equal state of perfection. This is the more surprising when we consider that a fluid-filled thick-walled organ like the heart, situated in the centre of a chamber largely filled with air, should be an ideal subject for the radiologist. It is true that X ray methods have been employed in cardiac examination, and orthodiagraphy has been, and still is, extensively used for the purpose. But this method has several disadvantages, and in my opinion the teleradiogram offers decided advantages over the older method.

The methods which can be utilised in the X ray examination of the heart are fluoroscopy, orthodiagraphy, "barium swallow" examination, and teleradiography in the erect or prone position. In this paper only the last will be considered.

METHOD OF PRESENT INVESTIGATION

In the X ray department of any chest hospital a large number of routine X ray examinations are made, some of them for the examination of the lungs and some of them on heart cases, and a method for accurate estimation of the heart's size and the size of its different chambers would therefore be very useful in the elucidation of the cases seen. To find out whether an accurate standard of heart measurement could be obtained, a large number of chest radiograms of apparently normal cases were studied, using first the method described by Vaquez and Bordet, which is at present used in orthodiagraphic

movement. If the exposure is more than one-tenth of a second the heart outline, especially on the left border, is liable to be blurred.

If all these details have been carefully attended to it will be seen on examining the film that the right dome of the diaphragm lies between the tenth and eleventh ribs at its point of maximum convexity, whilst the left dome is at a slightly lower level.

The clavicles are horizontal and their inner ends should be exactly equidistant on each side of the vertical column. If they are not equidistant, it will mean that the exposure has been made with the patient in a position of slight rotation unless scoliosis is present (see Case 2). When the scoliosis is of a moderate degree, mensuration can still be carried out on a routine radiogram or on a film taken after rotating the patient into alignment under screen control.

In valvular lesions there may be (1) changes in the outline of the borders of the heart, of which the most important is the left border; and (2) changes in the relations of the different measurements to each other.

(1) *Outline of the heart.*—The changes in outline caused by single valvular lesions are moderately well known, and a description of them is given in some of the more recent test books. Figs. 3 and 4 show tracings of the heart outline in mitral disease and in aortic disease, and it will be seen that whereas in mitral disease there is a convexity below the aortic knob, in aortic disease there is a concavity. A study of these outlines, which seem to be reproduced regularly in a radiogram, enables the type of valvular lesion to be determined with considerable accuracy in a simple case.

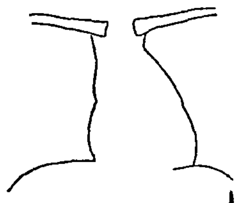

FIG. 3.—Early mitral stenosis.

(2) *Relation of the different measurements to each other.*—If the measurement LV is divided by the measurement LA an index LV/LA is obtained, which is of some value in differential diagnosis. In normal radiograms it varies between 1·7 and 2·0 in the erect view, and 1·6 and 1·9 for the prone position. Where a mitral valvular lesion is present the ratio is reduced, since the relative value of LA increases with enlargement of the left auricle and pulmonary artery. In extreme cases it may be as low as 1·3. When the aortic valve is also involved the ratio tends to have a normal value. The following list shows the alterations of the index found in different heart lesions:—

Aortic stenosis	Normal
Aortic regurgitation	
Mitral stenosis	Reduced
Mitral stenosis with aortic disease ..	Normal or slightly reduced
Mitral stenosis with tricuspid disease	Reduced
Pulmonary stenosis	

A study of the heart outline and the figures obtained by mensuration enables us in many cases to decide from the radiogram what valve or valves are diseased.

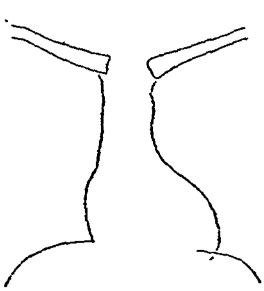

FIG. 4.—Early aortic valvular disease.

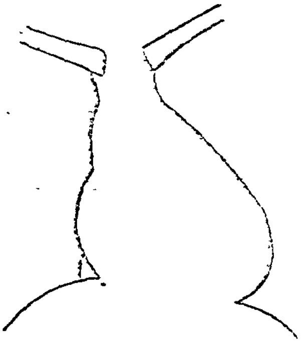

FIG. 5.—Mitral stenosis with tricuspid regurgitation.

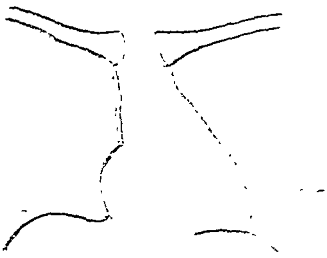

FIG. 6.—Pulmonary stenosis.

The position may be summarised as follows:—

Mitral disease (Fig. 3).—There is a prominence on the left border of the heart below the aortic knob, which increases with the development of stenosis of the valve. In advanced cases the outline of the left auricle is seen on the right border of the heart and encroaches on the root of the aorta. LA is increased and the ratio LV/LA diminished to 1·5 or less. Increase of the lung markings from congestion is frequently seen. A radiogram taken in the first oblique position will show the dilated left auricle.

Aortic valvular disease (Fig. 4).—The left ventricle is enlarged and protrudes downwards and outwards. The left border of the heart in the auricular region tends to be concave. LV and RV are increased and the ratio LV/LA is normal. Changes in the outline of the aortic arch can be confirmed by a radiogram taken in the second oblique position.

Mitral stenosis with aortic disease.—The heart outline usually resembles that seen in mitral stenosis. All the measurements are increased. The ratio LV/LA is normal or slightly reduced.

Congenital heart.—I have refrained from discussing the numerous forms of congenital heart disease, as the exact lesion is so seldom established with certainty ante mortem. If the pulmonary artery is enlarged the shape of the heart has some resemblance to that seen in mitral stenosis, the measurement LA is increased in size and the ratio LV/LA falls to 1·5 or less. An example of the outline seen in pulmonary stenosis is shown in Fig. 4.

ILLUSTRATIVE MEASUREMENTS

NORMAL CASES

CASE 1.—Female, aged [illegible]. Routine chest radiogram to exclude pulmonary tuberculosis.

Erect.		Normal.
TD	[illegible]	
LD	[illegible]

TD × LD ..	[illegible]	
Ao	[illegible]	[illegible]
Trans. diam. ..	[illegible]	[illegible]
LA	[illegible]	[illegible]
LV	[illegible]	[illegible]
RV	[illegible]	[illegible]
LV/LA	[illegible]	1·6—1·9

The measurements are close to the average, both in the erect and in the prone positions.

CASE 2.—Male, aged 23. To show the effect of rotation. Radiograms were obtained with the patient straight and also after rotating him slightly to the right and left oblique positions.

Erect.	
TD	[illegible]
LD	[illegible]
TD × LD ..	[illegible]

	Patient straight.	Normal.	Right oblique position.	Left oblique position.
Ao	3·1	3·3	2·9	3·4
Trans. diam.	12·6	12·5	12·2	12·6
LA	7·5	7·5	6·5	7·2
LV	14·7	14·5	15·2	15·0
RV	11·7	11·5	11·5	11·7

The aortic measurement is diminished in the first oblique position and increased in the second. The other measurements show some alteration, LV being relatively increased and LA diminished in the oblique positions.

VALVULAR LESIONS

CASE 3.—Female, aged 5 (Fig. 2).

Prone.		Normal.
TD	[illegible]	
LD	[illegible]	
TD × LD ..	[illegible]	
Trans. diam. ..	[illegible]	[illegible]
LA	[illegible]	[illegible]
LV	[illegible]	[illegible]
RV	[illegible]	[illegible]
LA/LV	[illegible]	[illegible]

LV and the transverse diameter are within 1 mm. of the normal, LA is increased by 1·1 cm. and the LV/LA ratio is diminished. If the transverse and longitudinal diameters of the heart only were measured, the abnormality would be missed.

The X ray diagnosis was mitral stenosis, which was in agreement with the clinical findings.

CASE 4.—Male, aged 14½ (Fig. 4).

Prone.		Normal.	
TD	23·5		
LD	16·2		
TD × LD ..	375		
Ao	2·3	2·4	—0·1
Trans. diam. ..	12·0	10·8	+1·2
LA	6·5	6·8	—0·3
LV	12·9	11·8	+1·1
RV	11·2	9·8	+1·4
LV/LA	1·89	1·60 —1·90	

The left border of the heart is concave below the aortic knob. The left ventricle is prominent. The transverse diameter, LV, and RV are increased more than 1 cm. The ratio of LV : LA is normal. The radiological diagnosis was aortic disease, which agreed with the clinical findings.

CASE 5.—Male, aged 27 (Fig. 5).

Prone.		Normal.	
TD	28·2		
LD	19·7		
TD × LD ..	555		
Ao..	—	—	
Trans. diam. ..	16·5	12·5	+4·0
LA	12·1	7·9	+4·2
LV	17·6	13·8	+3·8
RV	15·0	11·4	+3·6
LV/LA	1·45	1·60 —1·90	

Gross cardiac enlargement. The ratio of LV : LA is diminished to 1·45. Diagnosis: mitral stenosis with tricuspid regurgitation. Confirmed by autopsy.

CASE 6.—Female, aged 30 (Fig. 6).

Erect.		Normal.	
TD	23·8		
LD	16·2		
TD × LD ..	385		
Ao..	2·3	2·4	—0·1
Trans. diam. ..	12·5	10·2	+2·3
LA	8·4	6·0	+2·4
LV	13·0	11·5	+1·5
RV	11·7	9·3	+2·4
LV/LA	1·55	1·7 —2·0	

The outline of the heart is similar to that seen in mitral stenosis. It can be distinguished from mitral disease by the absence of enlargement of the left auricle. The radiological diagnosis of pulmonary stenosis agreed with the clinical findings.

I should like to take this opportunity of acknowledging the valuable assistance received from my colleagues at the Victoria Park Chest Hospital.

CLINICAL AND LABORATORY NOTES

POSTERIOR INFERIOR CEREBELLAR AND VERTEBRAL THROMBOSIS

By F. Holt Diggle, O.B.E., M.B. Vict., F.R.C.S. Eng.
HON. LARYNGOLOGIST, ANCOATS HOSPITAL, MANCHESTER; AND
John S. B. Stopford, M.D. Vict., F.R.S.
PROFESSOR OF ANATOMY IN THE VICTORIA UNIVERSITY OF MANCHESTER

THE interesting case of posterior inferior cerebellar thrombosis recorded by Prof. Hall and Dr. Eaves[1] prompted one of us to unearth records of a similar, though more diffuse, thrombosis.

CASE RECORD

A male, aged 76, suffering from complete dysphagia with pain and tenderness over the larynx and pharynx and constant cough from the irritation of unswallowed saliva, was seen in consultation and admitted to Ancoats Hospital on Oct. 22nd, 1929.

History.—During the previous two weeks several teeth had been extracted at intervals, the last extraction being performed five days before admission to hospital. There was no history of having swallowed a foreign body or bolus of unmasticated food. On Oct. 20th he noticed during the night that he was unable to swallow his saliva. This had continued up to the present time. He complained of pain over the pharynx, larynx, and trachea which was increasing. On Oct. 21st breathing was said to be "throaty" and phonation difficult.

Previous medical history.—Five years ago he was under the care of his own doctor with slight fits occurring about every three months, which in time disappeared. He had a paralysis once and this was most marked on the right side of the body.

Condition on admission (Oct. 22nd).—There was complete inability to protrude the tongue, accompanied by slurring of speech, and he was unable to swallow liquids. He complained of some tenderness over the larynx and trachea, and a constant cough, caused by the accumulation of saliva in the pharynx. There was complete paralysis and anæsthesia of the soft palate, paralysis of both sides of the tongue and bilateral pharyngeal constrictor paralysis, but the larynx was normal, the true vocal cords presenting perfect abduction and adduction. Owing to the patient's condition no further record of the state of the central nervous system was possible, but it is stated that the pupils reacted normally to light and accommodation. Blood pressure: systolic, 155; diastolic, 85. Wassermann reaction negative in a dilution of 1 in 5: urine, specific gravity 1015; acid; albumin +, acetone a trace.

Further progress.—Oct. 24th: patient appears worse. Fed yesterday with stomach-tube; appears too weak for this to-day. Respirations 36. Oct. 25th: patient seems slightly better; can now protrude tongue *slightly*, speech improved and he can be understood. Has had two feeds of a pint of milk by stomach-tube early to-day. This evening patient has started to swallow again and managed to get one pint of milk down in sips. A soft œsophageal tube readily passes into the stomach.

The patient slowly sank and died on Oct. 27th.

During the course of the illness the temperature never rose above 99° F., the pulse varied from 110 to 140, and the respirations between 32 and 36.

EXAMINATION OF BRAIN AND ARTERIES

Histological examination of arteries.—Sections were made of the basilar, the right and left vertebral and the right and left posterior inferior cerebellar arteries. All showed marked atheromatous changes of long standing. Atheroma was not so pronounced in the basilar as in the other arteries, but was most profound in the right posterior inferior cerebellar, which showed a lumen largely occupied by thrombus. There was also some thrombotic material in the lumen of the right vertebral and the left posterior inferior cerebellar arteries, but in none of these was the channel completely occluded. From both naked-eye and microscopical examinations of the arteries there was evidence of recent thrombosis following long-standing atheroma and that this had led to serious interference with the blood-supply of the medulla.

Sections of medulla were cut at three levels and stained to show the condition of the nerve-cells. The hypoglossal nucleus and nucleus ambiguus on both sides showed pronounced changes. The cells as a whole were badly stained and showed marked chromatolysis. Whereas a few cells exhibited a fair number of Nissl's granules and a central nucleus, most of them were almost devoid of granules and the nucleus excentrically placed. In some the nucleus was absent and the cell evidently in a state of advanced disintegration. Many of the cells were shrunken and deformed.

---

[1] Hall, A. J., and Eaves, Elizabeth, C.: THE LANCET, 1934, ii., 975.

The hypoglossal nucleus and the nucleus ambiguus seemed to be about equally affected on the two sides. The cells of the inferior olive stained much better and it was clear that the disturbance was chiefly in the retro-olivary region. There was clear evidence, also, that the upper part of the medulla had suffered more severely than the lower. The maximum effect was upon the upper parts of the hypoglossal nucleus and the nucleus ambiguus, and, to a lesser extent, on the upper parts of the dorsal vago-glossopharyngeal nucleus and the spinal nucleus of the fifth nerve on both sides. There was no evidence of softening or complete disintegration anywhere.

The histological appearances were consistent with the condition of the vessels and suggested an incomplete obstruction to the arterial supply of the upper medulla on both sides.

SUMMARY AND INTERPRETATION

In this case two things are clear from the pathological side:—

(1) There had been a long-standing and widespread atheroma of the intracranial vessels. This is evident from an examination of the vessels and the atrophic changes in the cerebral cortex, especially the frontal lobes.

(2) Recently thrombosis had occurred causing a "patchy" obstruction of the bulbar vessels with consequent changes in the medulla. The thrombotic material was most obvious in the lumen of both posterior inferior cerebellar arteries and the right vertebral, but histological sections showed a diffuse and widespread thrombosis in the finer intramedullary branches, especially in the upper part of the medulla.

On the anatomical side we have:—

(1) Profound changes in the cells of the hypoglossal nucleus and nucleus ambiguus on both sides. The severity of the lesion is about equal on the two sides.

(2) The disturbance is chiefly in the retro-olivary region and the upper medulla has suffered more than the lower.

(3) Whilst it is easier—owing to the larger size of the cells—to estimate the extent of the damage to the hypoglossal nucleus and the nucleus ambiguus, there is evidence which suggests that other nuclei in the retro-olivary region (such as the spinal nucleus of fifth nerve and the dorsal vago-glossopharyngeal nucleus) have not suffered so severely.

(4) The anatomical localisation is, on the whole, consistent with the pathological and clinical findings.

The long-standing character of the arterial changes and the patchy nature of the thrombosis demand great care in interpretation. It is not a clear-cut focal lesion from which we can deduce with confidence.

The most interesting points have reference to the nucleus ambiguus. The hinder part of this, which gives origin to the accessory portion of the spinal accessory nerve, has been called the laryngeal nucleus. This is because the accessory fibres join the vagus and later leave that nerve as the recurrent laryngeal branch which innervates all the intrinsic muscles of the larynx, except the cricothyroid. The sections prove that it is the cephalic part of the nucleus ambiguus which has suffered most, and the clinical report shows paralysis of the palate and pharyngeal muscles but not laryngeal muscles, which is consistent with escape of laryngeal nucleus (caudal part of nucleus ambiguus).

The arterial lesion is patchy and incomplete. We think this accounts for the fact that the nuclei appear to have suffered more than fibre tracts and also for the fact that there is no softening or complete disintegration. It may account for the absence of pupillary signs which are common in retro-olivary lesions.

Some disturbance of taste would be expected, but it was not possible to test this satisfactorily and therefore reference to it cannot be made. Paralysis of the tongue is accounted for by the bilateral lesion of the hypoglossal nucleus.

A dissociated sensory loss is almost the rule in such cases, but, owing to the condition of the patient, a satisfactory examination could not be made.

Lastly, it is difficult to explain the pain and tenderness over the larynx unless it is a manifestation of the involvement of the sensory tracts in the medulla. Its limited localisation makes such a suggestion a little unconvincing.

FRACTURED SPINE WITH FÆCAL INCONTINENCE

BY HAROLD DODD, M.Ch. Liverp., F.R.C.S. Eng.
SURGEON TO KING GEORGE HOSPITAL, ILFORD; SURGEON TO ROYAL HOSPITAL, RICHMOND

ON August 18th, 1934, Mr. A fractured his spine in a motor accident, the body of the first lumbar vertebra and transverse processes of the second and third on the left side being involved. He was admitted to a hospital (600 beds), where he lay on his back for five weeks without a splint or other method of immobilisation. During this time he was incontinent of fæces; it was dealt with by placing at the bedside a bedpan, which he passed beneath him when he felt wet. In the sixth week he was allowed up, and on Sept. 26th he returned home. He was able to shuffle comfortably, but could not lift his feet clearly from the floor. He had no control of his sphincter ani.

His doctor referred him to me with two queries: (1) When could he start work? (2) Did he need a spinal support?

The man protested that he was well, being keen to return to duty; he had a wife and three children. On inquiring about the action of his sphincters he admitted his fæcal incontinence. He entered hospital, where he was nursed on his face. His rectal sense and control returned immediately, but disappeared when he was turned on his back in order to use the bedpan, as the bowels acted before the receptacle could be introduced.

On Oct. 8th a Watson Jones plaster spinal jacket was applied; the result was immediate—his incontinence disappeared entirely. After a week he got up and was discharged home. For four or five days the incontinence returned while he was on his feet, but not when he was sitting or lying down (apparently the jacket did not completely fix the spine). During the following week the bowels acted three to four times a day, but rectal sense and control were established. The diarrhœa settled without treatment, and was succeeded the next week by pruritus ani, which disappeared with toilet measures.

He started work on Dec. 4th, but after four days he developed erysipelas at his right ear. He was admitted to another hospital, and it subsided. He restarted work on Jan. 14th, 1935, since when he has continued in good health. The plaster is still in position, that is, after six months. It is softening but is comfortable. It is to be replaced shortly by a light spinal support.

The case is reported for two reasons: (1) on account of its interest, incontinence being relieved by nursing on the face—that is, in extension. (2) Because it supports the method of treatment of a fractured spine so ably described and urged by Mr. Watson Jones.

VOLVULUS OF THE SMALL INTESTINE
HERNIATED THROUGH AN ABNORMAL ORIFICE IN THE MESENTERY

By Y. Cantin, M.R.C.S. Eng.

MEDICAL SUPERINTENDENT, CIVIL HOSPITAL, PORT LOUIS, MAURITIUS

A young Mahomedan shopkeeper, aged 27, was admitted to the Civil Hospital, Port Louis, on August 28th, 1934.

At about 11 A.M. on the previous day, immediately after his morning meal, he had been seized with violent pain in the lower abdomen, and an urgent but ineffectual desire to empty his bowel. He vomited his meal, but the pain, severe and intermittent, persisted throughout the day. An enema was administered to him in the afternoon, and some fæcal material but no flatus was returned. He vomited twice during the night, and was seen the next morning by a medical practitioner, who diagnosed perforation of the appendix, and advised his immediate removal to hospital.

On admission (about 24 hours after the onset of his illness) his condition was as follows. Body covered with clammy sweat; tongue moist, but features drawn and anxious. Pulse 140, poor; temperature, 37°C. (98·6° F.). Lower abdomen distended and not moving well with respiration. No rigidity, but diffuse tenderness over lower abdomen. No visible peristalsis. No borborygmi heard on auscultation. Liver dullness present.

On rectal examination some tenderness in Douglas's pouch.

There was a strong smell of acetone in the breath, and analysis confirmed the presence of acetone and of glucose in the urine (66 g. per litre). Twenty units of insulin were injected immediately, and shortly afterwards 20 c.cm. of 20 per cent. saline solution intravenously as a peristaltic stimulant. This probably initiated reverse peristalsis, for the patient immediately vomited bright green material. The acuteness of the onset, coupled with ineffectual tenesmus, suggested the possibility of a volvulus, and immediate laparotomy was decided upon.

The patient's condition, rendered still more precarious by the associated diabetes, led us to use local infiltration anæsthesia rather than give a general anæsthetic. Hyoscine hydrobrom. gr. 1/100 and morphia gr. 1/6 were injected as premedication, and after infiltration of the abdominal wall with 1/200 novocain a median subumbilical laparotomy was performed. As soon as the abdomen was opened, dark blood-stained serum welled out of the pelvis and gangrenous distended coils of the ileum came into view. The cæcum was felt to be empty. It was at first difficult to diagnose the exact cause of the obstruction, but on closer inspection a volvulus of the small intestine was discovered. The torsion was undone, and it was then found that the limbs of the loop emerged from a vertical slit, about 2½ in. long, in the mesentery, about 4 in. above the ileocæcal junction. The orifice was enlarged and the loop reduced. As the gut was not viable and the patient could not stand the resection of fully 2 ft. of gut, the affected loop was brought to the surface and drained, after stitching up the hole in the mesentery and the abdomen closed up. The patient died five hours after operation.

Hernia of the small intestine through an abnormal opening in the mesentery is rarer than its herniation through the transverse mesocolon. In a recent paper devoted to "Les hernies dites trans-mésocoliques," Ménégaux[1] was able to collect no less than 49 cases in which the ileum had often completely passed into the lesser sac through an opening in the transverse mesocolon. After reviewing the theories put forward to account for the existence of the abnormal opening—viz., perforation of a pre-existing peritoneal recess; trauma; fenestration during the process of development of a poorly vascularised zone of the mesocolon—Ménégaux sums up in favour of the last hypothesis as being the most satisfactory and as being also applicable to hernias of the ileum through an opening in the mesentery. In the case under review, the orifice did not correspond in situation to any of the peritoneal fossæ described in the neighbourhood of the cæcum, nor was there any history of trauma. Hence it is probable that the intra-abdominal pressure on the one hand and the aspiration exerted by the excursions of the diaphragm on the other led to the gradual ascent of a loop of ileum through a pre-existing orifice in the mesentery. This loop had secondarily undergone torsion, with resultant strangulation.

An almost exact replica of this case is to be found reported by Morestin in 1899 to the *Société de Chirurgie* and referred to by Lejars.[2] Morestin's patient however recovered; the gut was viable, and the surgeon confined himself to undoing the torsion and reducing the intestine through the hole in the mesentery.

MEDICAL SOCIETIES

ROYAL SOCIETY OF MEDICINE

SECTION OF OBSTETRICS AND GYNÆCOLOGY

The meeting of the section held on May 17th was devoted to a discussion on

Diet in Pregnancy

Mr. **Eardley Holland**, the president, who took the chair, said he had been anxious that this subject should be fully debated. He had always regarded it as one of first importance but it tended to be somewhat neglected by British obstetricians.

Dame **Louise McIlroy** said it had yet to be ascertained how best to feed a pregnant woman. Moreover, it was not easy to induce an interest in the problem. The two elements chiefly concerned, the mother and the ovum, ought to be as one; for the ovum should fit in with the metabolism of the mother, and the *feeding* should be the same for both; but there were warring elements, causing disease. When the ovum arrived in the uterus, the maternal metabolism became altered, even in the normal pregnancy. Nitrogen must be supplied for the enlarging uterus, and the demands of the fœtus would be met, even at the expense of the mother. In considering the mother's nutrition one must pay attention not only to what was ingested, but (even more important) to what was actually assimilated; it was always difficult to know why one woman easily assimilated the food she took, while another obviously assimilated only a portion. Another factor requiring notice was the placenta, which served as intermediary between mother and fœtus. From a study of metabolic aberrations one could work back to what was regarded as the normal, and the speaker believed that the vomiting, toxæmia, and hæmorrhages of pregnancy, and puerperal sepsis would prove to be deficiency diseases, and that the solution of some of the problems they presented would be found in the larder and the kitchen rather than the laboratory or pharmacy.

Of nutritional requirements in pregnancy the first was water, and the pregnant woman should take at least three or four pints daily, preferably fresh rather than boiled. Milk was a valuable article of diet, and Dame Louise could not understand why there should be so much outcry about the destruction of vitamins by pasteurisation when so little attention was paid to the cooking of vegetables, and to the disadvantages of living on preserved fruits, tinned foods, and other artificial diets. During normal pregnancy glycogen was stored in large quantities, and if the intake was seriously deficient, proteins and fats were drawn upon, and there might be vomiting and ketosis. A loss of nitrogen took place in early pregnancy, and the greatest retention was during the fifth and sixth months. This storage served to compensate for the hæmorrhage which would occur at parturition, and for lactation. The nitrogen was derived from meat, eggs, and fresh vegetables. In the second half of pregnancy, however, meat should not be taken; among better-class patients there was usually over-eating at this time, and the effect of excessive protein diet had to be countered by open-air exercise, and by taking more carbohydrates. The intake of fats should also be low; the pregnant mother should be told to avoid fatty (especially fried) foods, and should be content with one egg a day. Of vitamins the most important here were A and D, and it was best to obtain them from fresh foods. If the mother were given too much vitamin D the fœtus would grow excessively, while in large quantities this vitamin had a very toxic effect. The fœtal blood contained more calcium than the maternal blood, and to ensure a sufficiency it was well to administer calcium in a chemical compound. In women complaining of cramp, backache, and insomnia, calcium sometimes gave dramatic results. Iron was another essential: it controlled vomiting, and was very useful for morning sickness.

The situation could be summarised as follows. The pregnant woman must have a good mixed diet of fresh foods, including raw fruits and vegetables, a medium supply of proteins, and a small supply of fat. Every pregnant woman should walk two miles a day. Mostly the woman's state of nutrition could be estimated by her general appearance and by periodic weighing. A woman who was overweight would probably also be toxic. In the last six months of pregnancy she should gain about 3 to 3½ lb. a month, or 16 to 18 lb. in the six months. Women should be taught food values, and how to buy and cook vegetables, avoiding expensive artificial and tinned foods; the latter were bought largely to save trouble.

Dr. G. W. **Theobald** said that according to the dietetic deficiency hypothesis all the toxæmias associated with pregnancy were caused by an absolute or relative insufficiency of some substance or substances in the diet, the most important being calcium, and this insufficiency led to an inharmonious working of the various physiological processes of the body, and ultimately to hepatic dysfunction. The implications were: (1) that the toxæmias of pregnancy could be prevented; (2) that there was no essential difference in the mode of causation of any of them; (3) that renal symptoms were merely incidental, the kidneys playing no part in the causation of the toxæmias; and (4) that there was no such thing as a pregnancy toxin. While it was true that extensive destruction of liver, kidneys, and other organs might be found in association with eclampsia, it was equally true that significant histological lesions might be absent in the organs of women dying of eclampsia; hence he concluded that gross structural damage was incidental, and not causally associated with eclampsia. Hepatic lesions could be caused by taking a high protein diet which was deficient in certain factors. Why should eclampsia be peculiar to the pregnant state? The fundamental difference between the pregnant and non-pregnant states was that the fœtus robbed the mother of important substances; indeed, the fœtus was a true parasite.

Prof. S. J. **Cowell** said that in the middle months of pregnancy the mother was storing calcium at a greater rate than the fœtus; it was only in the last months that the fœtus was taking more calcium than the mother. A colossal storage of calcium took place in the last month, and this accounted for premature children being so liable to develop rickets. Adequate calcium storage depended on a sufficient supply of calcium and phosphorus in the diet and a sufficient intake of vitamin D. Prof. Cowell referred to an American investigation in which 188 pregnant women were given extra calcium and vitamin D; among these there were 2 cases of toxæmia. But among 230 cases to whom these extras were not given 30 women developed toxæmia. As for the child there was much experimental evidence that calcium feeding during pregnancy helped normal calcification of bones and teeth. The simplest plan was to make use of the naturally rich source of calcium, milk, and it was highly desirable for the pregnant mother to drink at least two pints daily. Other rich sources were cheese and green vegetables. Egg-yolk was rich in vitamin D, and cod-liver oil was a valuable addition.

Dr. H. N. **Green** said it was not yet known exactly what part diet played in resistance to infection. Vitamin A was apparently of greatest importance in this connexion, and in pregnancy the demand for it was increased. It seemed clear that the vitamin-A reserves of the woman in pregnancy were often lower than in the normal adult, and the septic cases showed lower reserves than did the non-septic cases. It was difficult to decide whether the low vitamin-A reserve was a predisposing factor, or was merely an effect of the disease; it might even represent a physiological stage in the puerperium. It was reasonable to ensure a good supply of vitamin A in pregnancy by giving moderate doses of some liver oil when the appropriate foods were not available. Low vitamin-A reserves were probably associated with low reserves of other nutritional factors. An important fact was the possible toxic effect of liver oil concentrates in large doses; this could be neutralised by large amounts of vitamin B. It was recognised that ample reserves were no guarantee against infection, but optimum supplies of vitamin A during pregnancy would reduce liability to a morbid puerperium. The final assessment of the value of vitamin A could be made in a scientific investigation in a country such as India.

Dr. Lucy **Wills** spoke on the nutritional anæmias in pregnancy. She divided her subject into nutritional anæmia due to deficiency in iron, and that due to the pernicious anæmia factor. The first of these was world-wide, the second was of great importance in tropical countries. Most industrial populations in this country had a diet containing 0·01 g. of iron, and that sufficed to keep blood values up. But it was not enough for women who sustained repeated pregnancies; hence a low-grade anæmia was common among such women, not only of the very poor, but also of the more fortunate classes. In some stock-raising regions of South America, hyperchromic anæmia was common—especially where hookworm disease was prevalent—but where rations of meat were taken that anæmia was much less frequent. Green vegetables and whole cereals should be taken by pregnant women, as well as red meat ration. The nutritional anæmia of pregnancy was a macrocytic anæmia, not idiopathic pernicious anæmia. It was due to a deficiency in the diet of Castle's extrinsic factor, and it could be prevented or cured by adding to the diet liver or liver extracts or marmite. The result of such additions was often dramatic.

Prof. JAMES YOUNG suggested that a committee might be appointed to consider diet in pregnancy and lay down dicta for pregnant women.

Mr. VIVIAN GREEN-ARMYTAGE spoke of complications of pregnancy by such diseases as osteomalacia, beri-beri, sprue, in all of which calcium was at its lowest ebb, though unaccompanied by toxic symptoms. Though apparently healthy at birth, babies should be cared for in the first months of life on anti-rachitic lines. One-fertility sterility was often traceable to dietetic defects, particularly in regard to minerals.

Dr. K. J. WESTMAN said that deficiency of vitamins B and A in the food might lead to premature labour, to abortion, and to children being deficient. In six cases in which women had habitually aborted, a living child was secured by adding calf's liver to the food.

Dr. DOROTHY C. WILSON referred to lack of sunlight in the causation of osteomalacia, and instanced a region in India in which pregnant women were very liable to that disease. It had been largely reduced by making alterations in the diet.

Mr. R. H. PARAMORE considered that excess of food was a potent cause of eclampsia. One of the best methods of treating post-partum eclampsia was by bleeding. Post-partum hæmorrhage was never followed by post-partum eclampsia.

Dr. DOROTHY LOGAN asked whether the cheaper baker's yeast was as efficacious as marmite; some mothers were so poor that even 6*d.* a quart for milk was a hardship. At an institution with which she was connected a custom had been carried out since 1920 of giving three pennyworth of calcium lactate in a fresh state to antenatal cases, and the cost of that was 6*d.* a fortnight. It was a method of guarding against a calcium drain at small cost.

Sir ROBERT ARMSTRONG-JONES, alluding to the proposal to appoint a committee on the subject, said the People's League of Health already had a committee on somewhat similar lines.—The PRESIDENT spoke favourably of Prof. Young's proposal, and promised consideration of it at the next meeting of the council.

THE SILVER JUBILEE IN SOUTH AFRICA.—As Governor-General of the Union, Lord Clarendon has initiated a Jubilee fund to be devoted to the combating of tuberculosis in South Africa.

MEDICAL SOCIETY OF INDIVIDUAL PSYCHOLOGY

AT a meeting of this society, held in London on May 9th, Dr. NEIL BEATTIE read a paper entitled

Individual Psychology and Preventive Medicine

Preventive medicine, he said, had already made immense contributions to the national health by its attention to environmental hygiene. But the realisation that health meant wholeness, "the integration, unity, and harmonious working of the complete individual," gave a wider and deeper significance to the function and purpose of the health services and of medicine generally. Mechanistic medicine was concerned with the treatment of diseased organs, but the higher form of medicine—human or philosophical medicine—regarded the patient in his entirety, not as a physiological machine but as a human being with a soul. The development of the infant body depended on wise care and feeding; but the growth and development of the infant soul depended primarily on its contact with mother or nurse. The failure to establish satisfactory contact with another human being was the cause of an egocentric or subjective attitude towards life; the possessor of this life-style grew up with an unreal, unalive personality and often "needed his fellow human beings only to exploit them." The reality of life, here on earth, was in Adler's view the solving of the problems of comradeship, work, and love; and the person who was living a complete, wholesome, and healthy life was he who had successfully solved this triple task. An egocentric life-style prevented a courageous approach towards reality; and since the self-centred person was always concerned with the preservation of his own ego, stress of circumstances frequently compelled him to take refuge in psychoneurosis, psychosis, delinquency, and even actual physical illness. While the medical technician merely treated a diseased organ, the educated physician knew that, in addition to such treatment, the patient frequently required to be set free from the fear of himself—that is to lose some of his egocentricity by the development of social feeling and courage.

The real purpose of medical education was the production of an educated physician; and this could only be achieved by showing the student how to understand and know himself, setting him free from the trammels of mechanistic medicine. The greatest contribution to human medicine, said Dr. Beattie, would be made by the influence of the properly educated family physician upon diseased bodies and souls. An even greater duty was associated with the real function of the doctor in the homes of the people, as a teacher of the way of wholeness, completeness, and integration—that is, of health and freedom. The building of healthy houses was excellent and useful work, but it was the healthy *home* which produced healthy children and potentially healthy men and women. The root cause of ill-health, both physical and mental, frequently lay in disintegrated, unhappy family life; and it was for the medical profession to realise that in its hands rested much of the cure and still more of the prevention of national ills. Any medical man or woman who remained blind to the tremendous significance of the teachings of modern psychology to the science and art of medicine was in great need of the help of the very branch of medicine which he pretended to despise, and of which he was really afraid.

REVIEWS AND NOTICES OF BOOKS

Medicine and Mysticism

By R. O. MOON, M.D., F.R.C.P., Consulting Physician to the National Hospital for Diseases of the Heart. London: Longmans Green and Co. 1934. Pp. 57. 2*s.* 6*d.*

Dr. Moon in reviewing the history of medicine, sees in its progressive advance through the last century, a development of the scientific spirit, with a comparative disregard of mystical influences. The great progress that has been made, has been largely due to the use of the inductive method enunciated by Bacon and carried into practical activity by Harvey, and other leading spirits of science. The tendency on the part of mysticism, particularly its oriental expression, has been to disregard the body or, at least, to accept it merely as a vehicle for the expression of the spiritual world. Dr. Moon states that science and mysticism "would both seem to be means of revealing truth but their method of procedure is strikingly different, the two psychic tempers are alien to one another."

If, however, one reviews the history of medicine particularly during the centuries of the Renaissance—as Dr. Moon does in a most illuminating fashion—we see that medicine and mysticism have by no means been divorced from one another either in theory or in practice. The influence of Plato and of Neo-Platonism in many ways had as profound an influence on the minds of certain medical thinkers as had the teachings of Aristotle upon others. In fact there were some such as Ammonius Saccas who attempted to profit from the teachings of both schools and to colour both with oriental mysticism and with Christianity. The ultimate goal of many thinkers was the pursuit of motionlessness—i.e., of "The One," rather than of thought, which is a form of motion and activity. Mysticism in medicine must be regarded as an attempt to see the universal in the particularity of bodily phenomena, and it is only by appreciation of the fundamental spirit from which life derives that bodily function and disease can be correctly understood.

It is surprising to what extent the Pythagoreans and the Orphics have influenced the thought of Europe and permeated the systems of medicine. Dr. Moon cites the well-known doctrine of the "Critical Days" which played an important part in the writings of Hippocrates and Galen, and which seemed reminiscent of the mystical properties that Pythagoras attached to numbers. Galen, Raimond Lull, and Paracelsus, Agrippa of Netterhein, and Van Helmont were all influenced by mystical doctrines, and even Harvey himself was not entirely immune from a mystical tendency in his interpretation of organic behaviour. Hahnemann was in the line of succession of Paracelsus and his homeopathy was a dynamic conception of drugs as containing spiritual powers which were brought to life during the rubbing together of chemicals in the pharmacist's mortar.

In our own time mysticism has attempted to oust medicine from its rôle of healer of disease, in the rebirth of the doctrine of faith-healing as expressed in Christian Science. Perhaps the only true mating of mysticism and medicine has come with the development of psychopathology, a fact which the author has failed to mention. There are some who would no doubt condemn psychopathology on this account. But the discovery that many disorders of function, not only of the mind but of the body too, are occasioned by deep instinctual urges which are at one with the vital impulse itself, proves that the philosopher physicians of the Middle Ages and the Renaissance were struggling in a diffused light, which has been focused to-day upon both mental and physical disorders in such a way that the scientific approach can make use of a mental philosophy without a loss of prestige.

We commend Dr. Moon's work to the increasing number of medical men interested in the making clear these fundamental problems.

Researches on Tropical Typhus

A Study of the Bacteriology, Serology, and Epidemiology of the Disease. By LUDWIK ANIGSTEIN, M.D., Ph.D., Parasitologist to the State Institute of Hygiene, Warsaw, Poland; Lecturer in Parasitology, University of Warsaw. Kuala Lumpur: Kyle, Palmer and Co., Ltd. Pp. 184.

TYPHUS is a world-wide disease and appears invested with distinctive and peculiar characteristics in the most diverse climates and under the most diverse conditions. It would be difficult to find an investigator better qualified to study this disease in its entirety than Dr. Ludwik Anigstein. After experiencing epidemics of typhus exanthematicus during the war, he was appointed to the State Institute of Hygiene in Warsaw and there had further opportunities of observing the disease from a laboratory point of view. Since 1929 Dr. Anigstein has been investigating tropical typhus in Malaya. In an exhaustive comparative study of the puzzling natural history and serology of old world and tropical typhus he has been able to prove that the human body louse does not play any part in the transmission of tropical typhus in Malaya, although it was determined by Weigl's ingenious method of intrarectal inoculation, that the virus multiplies in the gut of the arthropod and is fatal to it. The rat *R. rattus diardi* is undoubtedly the reservoir of infection in Malaya, and examination of the smear of the affected tunica vaginalis of infected rats showed rickettsia-like micro-organisms in great numbers. The main results of this excellent piece of research support the contention of W. Fletcher and J. E. Lesslar (1925) that there are two types of typhus: the K or "scrub" type—which is the same as tsugamushi disease—and the W or urban type.

Laboratory Medicine

A Guide for Students and Practitioners. Second edition. By DANIEL NICHOLSON, M.D., M.R.C.P. Lond., Assistant Professor of Pathology, University of Manitoba. London: Henry Kimpton. 1934. Pp. 566. 30*s.*

THE author has succeeded well in his aim to provide in detail, for medical students, information on the indication, method, and interpretation of diagnostic tests that would prove most suitable when they later engage in practice. The indications for the performance of any particular investigation are clearly stated and the interpretation is explained on the basis of general principles. Actual accounts of technique are confined to those procedures which the student may himself have to use in the course of his future career as a medical practitioner. It is a particularly valuable feature of the book that clear and detailed descriptions are given of the sort of specimen required for any particular investigation, and of the mode of collecting it. The unsuitable specimen is the bane of the laboratory worker. The medical practitioner who sent a blood smear in to his local laboratory with a request for the performance of a Widal reaction constituted an extreme example of a common type of error; others to our knowledge have expected a useful reading of the blood-sugar from an oxalated specimen, and of the blood-urea from one treated with fluoride. Readers of Dr. Nicholson's book will know better than this. It is significant of the march of clinical pathology that the author concerns himself not only with the examination of the specimen but also with its collection. Some of his hints are valuable—for example, to pass the Ryle's tube through a cocainised nostril rather than by the mouth. Clear details are given not only of the technique but also of the results to be looked for in such tests as the Schick, the Dick, and the Schultz-Charlton, which fall equally within the sphere of the clinically conscious pathologist and the pathologically minded clinician.

In the present edition fairly recent procedures such as the van Slyke urea-clearance test and the Aschheim-Zondek test for pregnancy find a place; the author describes the Friedmann modification, in which rabbits are used, to the exclusion of the original mouse method. The short section on water metabolism constitutes one of the most valuable in the book; it deals with an aspect of medical treatment too frequently neglected in this country. This section is not concerned with work at the laboratory bench; no single "test" or "reaction" is described, but everyone training for or engaged in the practice of medicine will find it profitable to ponder it.

Elementary Microtechnique

By H. ALAN PEACOCK, M.Sc., Head of the Biological Department, Cheltenham Grammar School. London: Edward Arnold and Co. 1935. Pp. 200. 5*s.* 6*d.*

THIS little book will be welcomed by many teachers of elementary biology. It sets out in a clear fashion the theories underlying microtechnique, of which more advanced students are often ignorant. The subject matter is so arranged and tabulated as to make it a useful book of reference.

The 1934 Year Book of Obstetrics and Gynæcology

Obstetrics. Edited by JOSEPH B. DELEE, A.M., M.D., Professor of Obstetrics University of Chicago Medical School. *Gynæcology.* Edited by J. P. GREENHILL, B.S., M.D., F.A.C.S., Associate Professor of Gynæcology, Loyola University Medical School, Professor of Gynæcology, Cook County Graduate School of Medicine. Chicago: The Year Books Publishers Inc.; London: H. K. Lewis and Co., Ltd. 1935. Pp. 717. 10*s.* 6*d.*

THIS small volume contains a mass of information, much of which is not to be found in standard textbooks. The original work published during the year has been summarised under appropriate headings, and the commentaries supplied by the editor are valuable and delightful. Prof. DeLee is occasionally terse and sometimes almost rude, but he gives the reader the unbiassed view and experience of one whose life has been devoted to obstetrics. What would otherwise be no more than a catalogue of recent work is converted to a stimulating review. The author's comments on the causes of maternal mortality and morbidity, and on the use of analgesic and anæsthetic drugs in midwifery will be appreciated by anyone who practises obstetrics. Gynæcology is dealt with by Prof. Greenhill in an exactly equally robust manner, and the probable success or inherent futility of any new treatment or investigation is ruthlessly assessed. The whole volume is by definition thoroughly up to date and the selection of material for inclusion is excellent.

This original and outspoken work deserves attention. For those who practise obstetrics there is practical guidance, for those who teach a commentary on their dogma, for those who learn direction for their thoughts, and for all an absorbing account of the changes that have occurred during the last three decades in the art and science of obstetrics and gynæcology.

The Problem of Mental Disorder

A Study undertaken by the Committee on Psychiatric Investigations, National Research Council. Edited by MADISON BENTLEY, Sage Professor of Psychology, Cornell University; and E. V. COWDRY, Professor of Cytology, Washington University. London: McGraw-Hill Book Company, Ltd. 1934. Pp. 388. 24*s.*

THIS book gives an excellent conspectus of the present state of psychiatric research. The outlook is optimistic but critical. The editors, with the support of the Carnegie Corporation, collected the views of the foremost workers in psychiatry in the United States. In the first section of the book current thought is presented by clinical authorities: Prof. C. Macfie Campbell and Dr. A. Myerson represent the general psychiatrists; Dr. I. S. Wechsler, Dr. Adolf Meyer, and Dr. L. S. Kubie the neurologist, the psycho-biologist, and the psycho-analyst respectively. All are temperate, all are distrustful of glib explanation. Their bias is, of course, medical; they refer always to clinical problems and look forward to therapeutic application of discovery. It is recognised throughout the work how little relevance treatment has at present to theory and to "sound and sufficient knowledge of the human organism, of its history, of its physiological and psychological operations, and of its devious and complicated career from birth to death among physical, domestic, and social hazards." Each of these contributors indicates the lines of research which he thinks fruitful.

The various sciences which must supply the assured basis of psychiatry are reviewed in the second and larger part of the book. Neural mechanisms and functions come first. Dr. Stanley Cobb deals with cerebral anatomy and physiology, Dr. George Bishop with the electrophysiology of the brain, Dr. E. Jacobson with the electrical measurement of activities in nerve and muscle, Dr. E. V. Cowdry with neurocytology, and Dr. Irvine Page with the chemistry and metabolism of the brain. After Dr. Wilder Penfield's contribution on cerebral neuropathology, and Prof. G. H. Parker's on phylogenetic aspects, Prof. C. Judson Herrick gives an exposition of the bearing of integrative studies on mental disorder. Problems of general biology and genetics are presented by Prof. H. S. Jennings, and of constitution by Dr. Walter Freeman. Dr. R. G. Hoskins considers the rôle of the glands of internal secretion. The neurocytotropic virus diseases, such as encephalitis lethargica, are the subject of a paper by Dr. E. W. Goodpasture; Dr. George R. Minot writes on nutritional problems, and Dr. K. K. Chen on pharmacology. Prof. Madison Bentley has a long, plain-spoken, and informative chapter on general and experimental psychology relative to the problems of mental disorder, in which he sketches the lines of profitable research; it is followed by a brief paper on the psychological avenues of approach to schizophrenia by Mr. D. Shakow, and by another on the psychoneuroses from the standpoint of the clinical psychologist by Dr. Joseph Jastrow. The comparative psychopathology of infrahuman primates is set forth by Dr. R. M. Yerkes and Dr. Ada Yerkes as an aid to the study of human beings. The sociological aspects of mental illness are presented by Dr. Mandel Sherman and Dr. Irene Sherman, and Prof. A. L. Kroeber writes on cultural anthropology. A chapter on education by Dr. Leta Hollingworth ends the book, except for the comments and reflections of the editors.

The book is valuable, not as an account of what we now know, but as a reminder of the many ways in which we may hope for illumination of our present ignorance; it is also a warning against the slipshod casuistry which has at times threatened to hold the psychiatric stage.

L'âge critique

Étude Pathogénique et Clinique. By G. MARAÑON. Professeur a la Faculté de Médicine de Madrid. Paris: Libraire Félix Alcan. 1934. Pp. 333. Fr.40.

THIS, the French translation of Prof. Marañon's Spanish treatise, is a complete account of the climacteric as it occurs both in the male and female. Information dealing with this important and common period of life can only be obtained, as a rule, from a search in works on endocrinology, gynæcology, physiology, or the like; but here in one volume is the latest knowledge available. Marañon considers that the climacteric is, as a source of illness, neglected and, by the medical profession as a whole, not treated with the respect and attention that it deserves. Six chapters are allotted to the action of the ductless glands and the symptomatology is divided according to the effect on the various systems of the body. These aspects have been considered at length, and it is most disappointing to discover only 17 pages allotted to the difficult question of treatment. As Prof. Marañon has evidently acquired a complete grasp of the subject we may hope he will consider enlarging this chapter of his most interesting book to at least ten times its present size in a future edition.

Urology

Third edition. By DANIEL N. EISENDRATH, M.D., Consulting Urologist to the American Hospital, Paris; Assistant Professor of Surgery (Genito-Urinary), Rush Medical College of the University of Chicago; and HARRY C. ROLNICK, M.D., Clinical Professor of Genito-Urinary Diseases, Loyola University Medical School. London: J. B. Lippincott Company. 1934. Pp. 942. 42*s.*

THE practitioner who reads this book or even glances through it, examining the illustrations and reading the headings, will find that with a minimum of trouble he has brought his knowledge of urology up to date. In this third edition the authors have incorporated all the advances that have been made during the last few years. The most notable amongst these is the introduction of excretion urography; in their opinion it is the greatest development in urology that has taken place since von Lichtenberg and Voelcker introduced retrograde pyelography in 1906. The fact that the intravenous method is within the reach of those who are not expert in urological manipulations has established it as a routine method of examination for most lesions of the upper urinary tract. According to this book, excretion urography will supply the diagnosis alone in 30 per cent. of such cases and prove a valuable aid in at least 60 per cent. But although the technique is simple, considerable experience is required in the interpretation of results. Pyelograms of different types of pelves and calices are supplied so that the inexpert may have a working knowledge of the wide variations within normal limits.

Another advance of the last few years has been the introduction of perurethral methods of treating prostatic and bladder neck obstruction. New sections have therefore been added on transurethral electroresection of the prostate and bladder neck. Whilst recognising the place of these newer methods, the authors adopt a somewhat conservative attitude towards them. They point out that, although surgery carries with it the danger of shock to the debilitated patient, intra-urethral manipulation may sometimes produce even greater shock. Especially is this so if instrumentation has been prolonged. Resection, therefore, should be carried out as rapidly as possible and be restricted to cases that come within its scope. Another important addition to the work is in the chapter dealing with renal calculi, where new paragraphs are devoted mainly to the differential diagnosis of renal from gall-bladder shadows.

The distinguishing features of this work are clearness of expression, appropriate classification, and profuse illustration, all qualities of vital importance in a book intended for purposes of rapid revision.

Blood Groups and Blood Transfusion

By ALEXANDER S. WEINER, A.B., M.D. London: Baillière, Tindall and Cox. 1935. Pp. 220. 18*s.*

THIS book contains little that has not already appeared in the works of Schiff, Steffan and Lattes. It offers in English a competent survey of the present state of knowledge in regard to the blood groups and will be of value to those to whom for linguistic reasons the original sources are not available.

Chirurgie du pancréas

By P. BROCQ, Professeur agrégé à la Faculté de Médecine de Paris, Chirurgien des Hôpitaux; and G. MIGINIAC, Professeur à la Faculté de Médecine de Toulouse. Paris: Masson et Cie. Pp. 427. Fr.75.

DISEASES of the pancreas do not loom big in the practice of the ordinary general surgeon. Although some chronic inflammatory conditions are probably more common than they are generally recognised to be, taken as a whole affections of the pancreas amenable to surgical measures are rather rare. Prof. Brocq and Prof. Miginiac have made of this organ a special study. Dr. Brocq has already written one of the best monographs on acute pancreatitis in existence; the scale and extent of his investigations are shown by the fact that the account of acute pancreatitis in this book is based upon clinical reports of no less than 468 cases. With the same thoroughness the other diseases of the pancreas have been investigated, analysed, and presented in a form easy and interesting to read, with numerous drawings and microphotographs.

This authoritative book can be recommended to all surgeons. It brings our knowledge of the pathology, treatment, and prognosis of pancreatic diseases up to date, and is the kind of work which certainly will not lie unconsulted upon the shelf.

NEW INVENTIONS

AN IMPROVED PORTABLE ORTHOPÆDIC APPARATUS

BY A. G. ORD, F.R.C.S. Edin.
HON. SURGEON, ROYAL HOSPITAL, PORTSMOUTH

SOME years ago I designed a portable orthopædic apparatus for use in manipulative and operative orthopædic practice; it has, I believe, been widely employed and its usefulness been unquestioned. But it had serious disadvantages, among them being: (1) it was heavy and cumbersome; (2) there was inability to secure X ray photographs of the legs from above and below with the patient in linear extension, and inability to extend the hip-joint or flex the knee-joint; (3) the head and body supports were difficult to adjust as their shape and design did not permit either of raising or lowering the head or applying shoulder spicas; and (4) there was no provision for arm extension. These are the difficulties which I have endeavoured to overcome by redesigning the whole apparatus so that it should offer better and additional facilities.

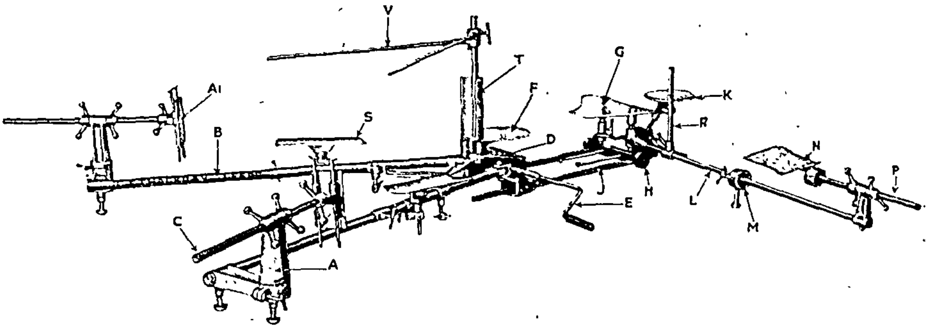

FIG. 1.—Shows the complete apparatus assembled, fitted with the arm extension.

The improved apparatus, like its forerunner, is made of aluminium, gunmetal, and steel, fits neatly into a specially constructed box measuring 37 in. by 21 in. by 11¼ in. The total weight when packed is 100 lb., of which the actual apparatus weighs 61 lb. only.

The improved apparatus is shown assembled in Fig. 1. The foot pieces (A) have been cranked out from the extension rods (B) to permit X ray photographs with the legs in linear extension; this also permits an extra adjustment allowing extension of the hip- and knee-joints, also an extra degree of abduction. The foot pieces can be rotated for eversion and inversion of the foot. Each foot piece is fitted with an improved type of foot plate (A1) and the extension screws (C) are now 18 in. long with quick travel threads. The combined pelvic support (F) and perineal guard (T) in two sizes is a new design and fixed at an increased distance from the central casting (D) to give more room for spica plasters. Overhead rods (V) are for maintaining flexion of knee when required. The pivot points of the hip-centring mechanism are now adjusted by a long crank handle (E), interchangeable for either side and also operating the moving racks (J) of the body support (G). Leg supports (S) have been remodelled and are instantly adjusted by an ingenious screw for height or distance. The body support (G) is an entirely new design. It is anatomically designed to the shape of the shoulders and is adjusted backward or forward by the crank handle (E) for different trunk lengths. The two small wheels (H) on its upright supports and the moving racks (J) make this adjustment rapid and easy when the patient is in position. Its greatest use is for the application of plaster spicas as the support can be quickly withdrawn after bandaging. The head support (K) is also a new design. It is saucer-shaped to conform to the contour of the head, provides complete immobilisation, and can be raised and lowered at will by adjustment of a swivel screw. Independently supported, it gives increased stability.

The arm extension (L) is an entirely new fitting, and can be used for either arm. The ball-and-socket movement (M) allows flexion of the arm. The hand plate (N), fitted with slots for bandaging, is also provided with ball and socket for dorsiflexion or volarflexion. An extension screw (P) gives extension in conjunction with an upright adjustable rod (R) for counter extension. I have found the arm extension invaluable for high fractures of the surgical neck of the humerus, the head of which is fixed with an awl, the arm extended and subsequently abducted. This manœuvre reduces the fracture which is at once fixed by a spica or other method. The ball-and-socket movement on the hand plate provides internal and external rotation of the humerus and pronation and supination of the elbow. Radial and ulnar flexion of the wrist-joint is also possible. Fig. 2 shows a patient in position on the apparatus with the limbs in abduction, right leg in extension and left leg externally rotated to give additional extension of the hip. Special spats it will be seen are used for extension. I have found these leather extension spats to be an immense improvement on bandaging the feet to footplates.

A special canvas stretcher has been devised which can be used with carrying poles if desired. The hooks and eyes of the original model have now been replaced with a modern type of zip fastener. After the patient has been placed on the stretcher the zip fastener can be opened, when the flaps can be completely opened back.

The improved apparatus has been made by Messrs. Chas. F. Thackray, Leeds, to whom I am much indebted for the able manner in which they have carried out my suggestions.

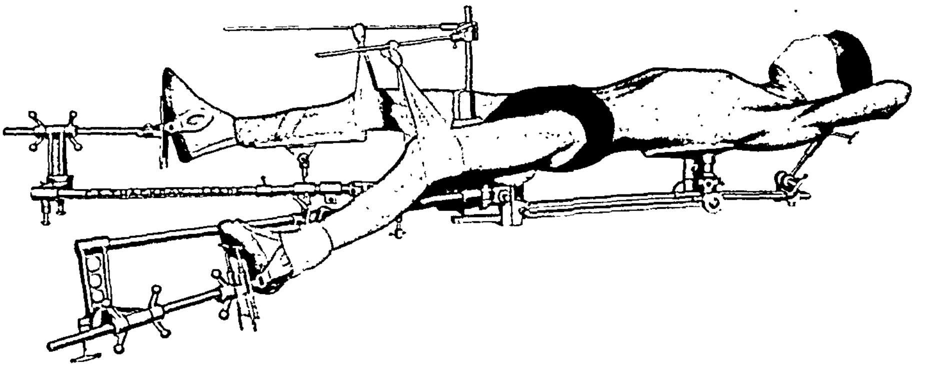

FIG. 2.—Shows a patient in position on the apparatus, with limbs in abduction, right leg in extension, and left leg externally rotated to give additional extension of the hip. Note special spats used for extension.

THE LANCET

LONDON: SATURDAY, MAY 25, 1935

RESEARCH IN PSYCHIATRY

THE study of mental disorder is just emerging from an unhappy phase of its development. Much neglected and over-simplified, it had become a centre of polemics about method and interpretation before its problems were defined. Available facts were ignored, and available methods contemned; partisan feeling stood in the way of fruitful research; argument took the place of demonstration, and the plausibility of a hypothesis was more important than its verification. The causes of all this are not altogether obscure. Psychiatry embraces conditions ranging from gross madness to inconspicuous peculiarities of disposition, and it is not easy for any one man to become familiar with the whole of this range of material. In England, indeed, it was almost impossible in the early years of this century until HENRY MAUDSLEY's plan was made actual after the war. There was no psychiatric clinic providing the means for acquiring such familiarity—no acknowledged centre of research and clinical experience which should be normative and materially disinterested. The problems of psychiatric research, moreover, proved to be not only complex but in some ways alien to medical modes of thought. Scientific methods profitably applied elsewhere in medicine seemed in the main sterile here beyond a certain point, while newer scientific methods appropriate to this study were not brought into touch with living clinical psychiatry. For one novel mode of approach, the psycho-analytical, undue claims were made. A study, such as that of psychiatry, which seemed to be vague, contentious, and scientifically stagnant, did not draw many workers trained for research. Many psychiatrists thought of the subject in terms of a false antithesis; description or investigation, custody or treatment, understanding or diagnosis, psychiatry or medical psychology: these were the spurious watchwords which darkened counsel. Groups of physicians espoused causes to an extent obsolete in other branches of medicine. It was asserted on the one hand that the only fruitful line of investigation was that which could be carried on in the consulting-room and was indistinguishable from treatment; others were equally confident that only in the laboratory, and without any use of the clinical worker's body of knowledge, could advance be looked for.

In medical practice many of these views and turmoils still persist. But in research that phase is almost done with; there is now more activity and less casuistry, more suitable choice of methods and not so much of the "get rich quick" attitude. Attempts are being made along many convergent lines to clear up the obscurity about these illnesses, these disturbances of harmony within the organism as well as between it and its environment. So a survey, reviewed elsewhere in this issue, of the outlook for research in psychiatry, which is sponsored by the Carnegie Corporation and the National Research Council in the United States, is timely. The editors have enlisted a most distinguished group of psychiatrists and other investigators to examine the prospects for research. Those among the contributors who are in touch with the clinical material are of like mind with Sir THOMAS LEWIS in their insistence that the research must start from the actual problems of disease and must return thereto, though the methods be borrowed from other sciences. Research in psychiatry by those who know nothing of psychiatry is apt to be fruitless because irrelevant. Here questions of organisation and more particularly of training arise; even the representative of the psycho-analysts in the symposium considers that the most serious handicap to the progress of knowledge lies in the "totally inadequate training" which many psycho-analysts have had in the associated fields of neurology and psychiatry, as well as in their own special discipline. The supporting sciences must be the means of fresh advance and the guarantee of its stability. Some of them deal with minute observations, others with the coördination of large bodies of fact. The former are the more precise, the latter the more significant, but the division is not sharp; all find their place in the framework. There is the physiology of neural mechanisms and functions, which may be concerned with electrical, chemical, structural, integrative, or embryological aspects of this complicated apparatus. There is the *biological* study of heredity and constitution, now continually freshened by discoveries in the non-human field. Special methods of investigation have been developed in pharmacology, in work upon nutrition, upon viruses, and upon the endocrine system, which can be applied here. Psychology, formerly remote and sterile, is no longer an armchair pursuit or arid scheme, but a well-based, manifold, growing branch of experimental science, averse from loose speculation and distrustful of the haze that sometimes passes for "medical psychology." It is itself relevant to psychiatry and contributory to further knowledge; psycho-analysis is only one of its branches, and an uncertain one. From the behaviour of infra-human primates, moreover, as from the data of cultural anthropology, psychopathology is likely to be fructified. Man must be studied in his social setting by psychiatrists, for maladaptation is the very touchstone of mental disorder. Sociology, statistics, and education are invoked for their contributions, enormously valuable so long as statistical and other controls are rigorously brought to bear on them.

These are not merely hopeful fantasies, but records of present activity. The results are still few because the problems are unusual and difficult. [illegible] results as have been established can only to a limited extent be translated, as yet, into treatment and prevention, is not astonishing. Psychiatry, as one of the most complex problems in biology, cannot hope to be exempt from the patient labour that must precede before even a limited mastery over complicated forces is attained.

INSURANCE CLAIMS AND ACCIDENT CASES

THE facts that are coming to light about the economic aspect of the treatment of patients who are the victims of accidents have a deep significance for the community. Orthopædic surgeons have for years been urging the importance to patients and employers of efficient treatment in the avoidance of permanent disability; their success has been marred, partly by inefficient organisation in most hospital centres, and partly by lack of financial support. It seems that it must now be only a matter of time before the insurance companies awake to the fact that they are paying out in compensation for time off work and for permanent disability sums out of all proportion to the amounts they would expend in directly financing, in part at least, the treatment of their clients by efficient methods. The State of New Jersey, U.S.A., has found this out and, as we have noted in a recent article (THE LANCET, April 6th, p. 817), taken appropriate action. The same lesson is to be learnt from the report of the working of the Accident Hospital in Vienna, for the building, equipment, and running of which the national insurance companies are responsible. LORENZ BÖHLER in the fourth edition[1] of his "Treatment of Fractures," now available in an English translation, deals in an addendum with the economic aspect of fracture treatment.

All those whose work has to do with accident insurance would do well to read Prof. BÖHLER'S book and learn such facts as this. In the year 1929 the maintenance cost of the hospital was 396,000 Austrian schillings. The saving on total compensation paid to 124 cases of fractures of the long bones treated in the hospital during that particular year, as compared with the compensation that would have been paid to the same cases in 1911, was reckoned at 370,972 *sch.* The figures tell the story plainly, especially when it is pointed out that, as well as these 124 fracture cases, 6000 other patients were treated in the hospital for the total maintenance of 396,000 *sch.* Two types of accident particularly interest insurance companies in general—viz., industrial accidents coming under the Workmen's Compensation Act, and third-party accidents on the road. It is the problem of the injured workman that has been the particular concern of the Austrian insurance companies. An impoverished country could afford neither the economic waste of having thousands of its workpeople attending physical therapy clinics for months or years when they might be usefully employed, nor the vast sums expended annually in compensation. In our country insurance against road accidents has added to the already very great financial interest of insurance companies in the correct treatment of accident cases. If, as seems possible, the cost of repairing injury to the person as well as to the vehicle in every accident is eventually covered by insurance, the problem will loom even larger. As it stands now, the hospital bill in certain claims only is met by insurance, while more often than not the surgeon's work is done for nothing. As Prof. HEY GROVES puts it,[2] "the car is paid for, but the patient's bones have to be mended as a matter of charity."

There are three types of personal injury in which skilled attention, from the first reception of the case at an accident clinic to its final discharge, are of great importance. These are fractures, especially of the long bones and of the spine, tendon lesions, and injuries of the hands. Prof. BÖHLER quotes figures which emphasise the economic importance of the last-named. In 1911 the Workers Accident Insurance Company in Vienna paid in compensation for fractures of the long bones 2,875,418 *sch.*, and for 2905 injuries of the fingers 3,859,466 *sch.* Every open wound of the hand, and every injury to the tendons, is a potential cause of crippling, and in any worker using his hand for skilled labour a potential claim lies for permanent loss of work. Yet the casualty department of a hospital, in charge of an officer without mature experience and not necessarily with any special skill in accident work, is usually considered a suitable place for the treatment of these cases. This is the accepted procedure in this country; BÖHLER'S plan is for the doctor who first deals with the case to be responsible for the treatment throughout, and even to write the final report, thus verifying the success (or otherwise) of his treatment. This seems reasonable, but it necessitates the placing of accident clinics in charge of paid officers who are skilled at the work, and some of whom at least must be on a full-time basis. The money needed to organise such clinics is at present being wasted on unnecessarily prolonged treatment, and in large sums for permanent disability. The victim of a Colles's fracture of the wrist, for example, can be back at work in about one quarter of the time if efficiently treated throughout and, according to figures quoted by HEY GROVES, the average percentage of permanent disability can be reduced from 23·6 to 0·4. It has been objected to the organisation of such clinics that pressure could not be put on insured persons to use them. No compulsion is exercised in the Viennese hospital and yet the scheme has been a success. Workmen insured by the company have the right of treatment at the hospital, but they are not forced to attend there. The building and equipment of the hospital, including the provision of X ray plant and other apparatus, cost £10,200. If the insurance companies concerned in the payment of accident claims were convinced that the cash saving for time off work, for prolonged treatment, and for permanent disablement was as material as in fact it would appear to be, the proper organisation of accident treatment would soon be put on a sound basis in this country.

MALARIA AND RACIAL EXTINCTION

From time to time historians have invoked the spread of malaria to explain the decline of human populations. Usually the changes in question have taken place so long ago that this hypothesis is not susceptible of proof. But on another page of this issue will be found a remarkable paper by Dr. A. J. Copeland which contains evidence that within the last few years certain of the peoples in North Borneo have begun to fall victims to this fate. There are two native races in North Borneo, each numbering rather less than 30,000: the Dusuns, an agricultural, rice-growing people, inhabiting the more open higher lands; and the Muruts, who inhabit the jungles at lower levels and live mainly by hunting. Whereas the Dusuns are on the whole a thriving race whose numbers are on the increase, the Murut population has been falling steadily during the past eight years, and Dr. J. G. Campbell is quoted as stating that "unless given systematic and energetic medical aid" this race is "doomed to slow but inevitable extinction." The decline of the Muruts is ascribed by Copeland to malaria. The village headmen state that there have been more cases of fever in recent years; there have undoubtedly been extensive clearances of jungle; and the imported Javanese labourers are believed to have brought with them strains of malaria parasite, particularly subtertian strains, to which the Muruts are not accustomed.

A prima-facie case is made out in favour of this view. It is regrettably true that after all these years new land in the tropics is still recklessly opened up by planters or engineers without consulting the malariologists; and thereby their employees and the local population are often needlessly exposed to malaria. There are, however, some missing links in Dr. Copeland's chain of evidence which must be filled in before his theory can be regarded as fully proved. The official vital statistics which he quotes, showing death-rates as low as 14 or 15 per 1000, can hardly be taken as accurate. And then it is generally believed, though the relevant facts are extraordinarily hard to obtain, that hyperendemic malaria reduces the population by causing heavy infantile mortality; whereas Copeland seems to attribute the reduction in the numbers of children chiefly to a lower birth-rate. Nor is there any evidence, though it is certainly likely, that recent clearances have in fact favoured the dangerous species of anophelines. The decrease in native populations is often due to subtle influences of an imponderable psychological character. Some races seem unable to thrive in contact with advancing civilisation; and this inability is apt to be more pronounced in a hunting than in an agricultural people. Such a failure of adaptation is the most probable cause of the decline, for example, of the Sakais of Malaya.

Dr. Copeland's thesis is nevertheless suggestive, and clearly demands examination. His paper gives a vivid picture of how medical work is carried on by a sympathetic medical officer among primitive peoples, and it incidentally illustrates once more the propagandist value of yaws treatment in popularising western medicine. To improve the malaria situation he encountered he proposes the wholesale distribution of quinine, and certainly the present issue is hopelessly inadequate; but it would be unduly optimistic to expect native villagers to take enough quinine to eradicate the disease. However popular the remedy, quinine treatment would have to be associated with a study of the mode of life of the Muruts, with a view to inculcating habits of clearing, housing, and living which will do something to preserve them from malarial infection. And it is to be hoped that Dr. Copeland's observations will stimulate the Government of North Borneo to undertake work along these lines.

ANNOTATIONS

INSTITUTE FOR MEDICAL RESEARCH, OXFORD UNIVERSITY

The statute establishing an Institute for Medical Research at Oxford, recently approved by Congregation, represents the latest development of a scheme which had its origin about five years ago. At that time Lord Nuffield—then Sir William Morris—bought the whole of the Observatory grounds and buildings from the Radcliffe Trustees for the sum of £100,000 and handed them over to a body of trustees, called the Morris Trustees, for the joint benefit of the Radcliffe Infirmary and the university medical school. It was indicated in the trust deed that the greater part of the land was to be used for the needs of the infirmary and for such extension of that institution as from time to time might become necessary. On the other hand, the Observatory buildings, the Observer's house, and a considerable area of surrounding land was assigned to the university for the purpose of promoting clinical research. The trustees also had in mind the possibility in the future of a ward, devoted to clinical research, which could be brought under the general administration of the infirmary in regard to its upkeep and nursing, with the proviso that it should not become an additional expense nor a source of profit to the institution. In order that the university should take advantage of the opportunity and accommodation provided by Lord Nuffield's great generosity, a scheme for the establishment of a Medical Research Institute was drawn up by the board of the faculty of medicine. The university has shown its desire and willingness to assist the scheme officially by providing the sum of £1000 per annum until such time as the institute is sufficiently endowed to run on its own resources. The board of the faculty of medicine have agreed that a recent bequest amounting to £30,000, generously made to the university by the late Mrs. Theodore Williams, should be used for endowment, and there are smaller sums available from other sources. Lord Nuffield has shown his interest and further generosity by offering to help towards the expense of altering and equipping the Observatory building for its new purposes.

The Observatory buildings become vacant in June and it is intended to use them for two lines of research—namely, therapeutics and X ray cinematography. There has been little organised research in therapeutics in this country and no place where drugs used in medical practice can be subjected to independent and searching tests by pharmacological as well as clinical methods. It is hoped that Prof. J. A. Gunn, as director of the institute, with the facilities afforded by his pharmacological department and with the ready coöperation of the medical staff of the infirmary, will be able to fill many gaps in our knowledge of the action of drugs and to open new lines of advance in their clinical application. At first sight the connexion of X ray cinematography with therapeutics may not be obvious, but the former is a new scientific instrument which promises to throw light not only on clinical but on anatomical, physiological, and pharmacological problems. The recent developments of this technique by Dr. Russell Reynolds in London, and by Dr. R. Janker of Bonn in Germany, are indicative of its future value both in research and in teaching, and further progress may be expected from their exploitation in connexion with the sciences ancillary to medicine.

It may be justifiably hoped that the establishment of a medical research institute at Oxford, even though it begins in a modest way, will help to meet the generally admitted need for such units in this country. There are always a certain number of medical men and women who are drawn towards research in preference to practice, who spend some years in training for research, and who are obliged to desert it because there are open to them so few posts which give them the necessary facilities as well as an adequate stipend. There is every possibility, too, that this unit may encourage closer coöperation and more combined effort in attacking problems which are of common interest to the staffs of more than one scientific department in the university.

THE EFFECTS OF HOT CLIMATE

In a paper read to the Royal Society of Tropical Medicine and Hygiene last week Dr. D. H. K. Lee drew attention to the urgency of problems connected with the settlement of tropical countries by peoples unaccustomed to the climate. The physiological effects of the heat itself although of great importance were, he thought, imperfectly understood. Some idea of the causes of breakdown could however be gained by combining our knowledge of the physiology of temperature regulation with the signs and symptoms of certain non-infective tropical disorders and the particular circumstances accompanying their onset. In recalling the ways in which the body keeps its temperature constant, he mentioned one or two points which are frequently overlooked. The body can increase its heat loss by dilatation of the skin vessels, allowing greater opportunity for radiation and conduction, and by activation of the sweat glands, causing cooling by evaporation. Dilatation of the skin vessels means an increase in the systemic vascular bed, and is accompanied by an actual increase in the blood volume which draws on the water stores of the tissues. Effective perspiration, which is the more important cooler, also depends on a sufficient reserve of water. There is thus a definite link between dehydration and temperature control. The complementary method of keeping down temperature by reducing the amount of heat produced is effected not only by an involuntary decrease in muscle tone or voluntary abstention from muscular exercise, but also by a diminution of the activity of the thyroid, suprarenals, and sympathetic nervous system, whereby the basal metabolic rate is reduced. Less food is then required and artificial stimulation of appetite becomes inadvisable.

Physiological adaptation to the effects of heat may, according to Dr. Lee, break down at four points.

(1) *Hyperpyrexia.*—A certain raising of the temperature on exposure to heat is not unphysiological so long as there is time for the readjustment of equilibrium to meet the new conditions. A progressive unchecked rise is a sign of failure of adaptation, and the result depends upon whether artificial lowering of the temperature can be achieved before some vital tissue becomes damaged. Neuroglobulin is precipitated at 108° F.; something less than this may be regarded as the critical temperature. There are naturally many predisposing causes of hyperpyrexia, but inhibition of sweating would be by far the most powerful, and is in fact met with in many cases of "heat stroke." The symptoms are well known.

(2) *Circulatory failure* is encouraged by heavy meals, alcoholic indulgence, continued standing, and emotional disturbance—in fact, by anything requiring a considerable redistribution of blood in the already enlarged and adjusted vascular bed. The symptoms include fainting, nausea, dyspnœa, and exhaustion, and may be grouped as "heat prostration."

(3) *Electrolyte imbalance* (to whose importance Lieut.-Col. O. R. McEwen has recently called our attention) is seen chiefly as chloride loss, due to excessive sweating and the replacement of fluid by pure water. Symptoms occur when the serum chloride falls below 100 mg. per litre; they consist of painful muscle cramps often preceded by a day or two of general malaise. The treatment is the administration, intravenously if necessary, of sodium chloride, and prophylactically the daily output of this salt should not be allowed to fall below 3 grammes.

(4) *Super-dehydration* can only occur where water is unobtainable, and its effects are many. First the symptoms of circulatory insufficiency may appear, but are replaced by the more serious effects of direct deprivation of water in the various organs, and are often complicated by a rise of temperature.

Under each of these headings Dr. Lee presented a table correlating physiological effects with clinical manifestations; in each case the essential features of the syndrome are accompanied in lesser degree by one or more features of the other types of disorder. He has undoubtedly cleared the air by deriving certain principles from a mass of confusing and incomplete data, and his analysis should lend direction and impetus to the study of heat adaptation.

PSITTACOSIS

Despite an embargo on the import of parrots occasional cases of psittacosis have been occurring in this country ever since the subsidence of the 1929–30 epidemic. And the same thing has been happening elsewhere. In Germany, for instance, Fortner and Pfaffenberg[1] have reported nearly 150 cases during the first half of 1934—an incidence little different from that of 1930. Almost without exception these cases have arisen as the result of contact with budgerigars (love-birds), and although it is known from the work done in 1930 that the budgerigar can suffer from psittacosis and infect man, the disquieting thing about these recent outbreaks is that the birds responsible have seemed to be in good health. That an apparently healthy parrot, a carrier of the virus, can give rise to human infection was shown by the investigations of Bedson, Western, and Levy Simpson[2]; and it is also known that carriers of psittacosis virus occur amongst home-bred budgerigars (Gordon[3]). In a paper published in our present issue, Dr. Levinthal produces further evidence that man can be infected by apparently healthy budgerigars (virus-carriers) and that a proportion of home-grown stocks of these birds is infected. As he points out, the budgerigar is probably less susceptible to the virus of psittacosis than other species of the parrot family and when naturally infected tends to become a carrier rather than a frank case of the disease. He also suggests that during the 1929–30 epidemic, when infected parrots were broadcast throughout the country, many of the stocks of home-bred birds became contaminated and that the infection persists to-day. Whether this view is correct or not—and there is much to be said in its support—the fact remains that the home-bred stocks are infected and that cases of human psittacosis are occurring, though fortunately there are very few of them.

[3] Gordon, M. H.: Ibid., 1930, i., 1174.

Not only should the public be aware of the danger but the medical profession should be on the look-out for cases. Without going into the differential diagnosis, it may be said that psittacosis should be suspected wherever there is an acute febrile illness in a person who has to do with budgerigars, especially if it presents the picture of a toxic pneumonia. In endeavouring to reach a correct diagnosis the laboratory can help,* and though the virus is present in the blood stream during the early days of the disease and can be demonstrated there by mouse inoculation, the sputum is the material of choice. Virus is quite constantly present in the sputum and its presence there can be established by mouse inoculation. Unfortunately sputum is not always readily obtainable for its scantiness is a feature of the disease, but usually with a little patience a satisfactory sample can be procured. Failing the demonstration of virus in material from the patient, specific antibodies may be sought in the blood, making use of the complement-fixation test elaborated by Bedson.[4] In this connexion it must be pointed out that specific antibody is not always developed and never in large amount; and of course this complement-fixation test, like any other serological reaction, has not the same value as isolation of the causal agent. Another line of investigation which may provide valuable evidence is the attempt to demonstrate psittacosis virus in the birds with which the patient has been in contact. This should be done even though they seem to be in good health; but it should not be forgotten that the finding of psittacosis virus is nothing more than circumstantial evidence that the human case is due to the same agent.

Concerning the virus itself, Dr. Levinthal's paper does not perhaps carry us much further. He holds that he has established definitely that this virus is the true causal agent of psittacosis because he has grown it outside the body in tissue culture and produced the disease with culture virus. The observations are interesting, but it is arguable on the other hand that virus grown in cells in vitro is no more a pure culture than virus grown in the cells of a living animal (such as the mouse) which does not suffer spontaneously from psittacosis. Hence there is room for difference of opinion over the claim that he is the first to show that this virus fulfils the postulates of Koch. He also differs from Bedson and Bland,[5] and Bland and Canti [6] in interpreting the relationship which the different virus forms bear to one another, taking the view that the elementary bodies are capable of multiplication without necessarily passing through large and intermediate forms. Whether or not he is right it is impossible to say from the evidence at present before us.

BRITISH SOCIAL HYGIENE COUNCIL

A LETTER published in THE LANCET of March 23rd last from Lord Horder and a representative group of co-signatories sets out the urgent need of the British Social Hygiene Council for further pecuniary support on arrival at its twenty-first birthday. A frank statement at the last annual general meeting of the Council concerning its financial position, no less than Lord Horder's letter, has paved the way for a special appeal for money. The voluntary sources of the Council raised from previous appeals are exhausted, and the funds show a considerable annual deficit. Considering the great objects before the Council and the success which can be attributed to its work in many directions, it is sad to contemplate that its efforts may be compelled to cease through lack of pecuniary support. Lord Stanley of Alderley has come out as chairman of an appeal committee, stating that this is the first organised appeal made by the Council and that £100,000 are needed. The forcible argument in his appeal is that the present generation is paying for the ignorance of its parents, and that since 1914 the Council has striven, in behalf of the present and future generations, to mitigate the tragedies among us, to root out their causes where possible, and to exterminate the evil influences perpetuating them. Lord Stanley of Alderley writes: "Since 1914 the British Social Hygiene Council has helped to reduce such cases by 57 per cent., principally by preventive education to the parents of the future generations, and it can continue this work until Britain is cleansed of the scourge—if you will help." The replies to the appeal should be made to Lord Stanley of Alderley, Appeal Committee B.S.H.C., 17, Dartmouth-street, London, S.W.1.

With the letter of appeal a brochure is enclosed entitled "Safeguard the Youth of the Nation and protect the Next Generation." It is a graphic summary more particularly of the work already done by the Council as an outcome of the report of the Royal Commission on Venereal Diseases. It is pointed out that the social hygiene activities of the Council, by stirring up the public health conscience, should lead to the reduction not only of venereal disease, but of many other scourges. That active health policy needs an understanding of human biology is a plea for support of the Council that none can gainsay, and as a campaign in this direction the proceedings at the Seventh Imperial Social Hygiene Congress to be held on July 8th to 12th, 1935, should be of great practical value. The congress is under the direct patronage of the Minister of Health and the Secretaries of State for India and for Dominion Affairs, as well as of the President of the Board of Education and many high Commissioners from the dependencies. The subjects to be introduced by inaugural addresses or discussed in conference are the relations of the teachings of sex behaviour to religious ethics, modern experiments in the field of social hygiene, biology in relation to social welfare, and juvenile delinquency. Immediate social problems within the Empire form the theme of one of the sessions, while in others the latest advances in the treatment of venereal diseases and the problems met with in the teaching of biology will come up for consideration. Membership tickets for the Congress are issued at £1 each, and should at Carteret House, Westminster, the offices of the Council.

A summer school will be opened at Westminster College, Cambridge, from Tuesday, July 30th, to Tuesday, August 6th, the inspiration here being the following words in Sir George Newman's report for 1933, as chief medical officer of the Board of Education. Speaking of emotional training and sex education Sir George said: "It seems reasonable that, at the present day, some appropriate instruction and guidance should be provided before children leave school, either as part of elementary biology or hygiene or otherwise." The Council is endeavouring to carry out the ideas embodied in that sentence, and at the summer school at Cambridge, Sir Walter Langdon-Brown, regius professor of physic in the University, and Mr. Z. F. Willis, assistant general secretary, National Council of Young Men's Christian Associations, will be among the prominent supporters. Courses of lectures include a series by Dr. L. J. Bendit, assistant physician, Institute of Medical Psychology, by Dr. Grace Calver, physician to the children's department of that institute, and Mr. P. F. Lee, B.Sc., education officer, B.S.H.C. The fee for membership of the summer school is £1 1*s.*, and the boarding fee from tea-time on July 30th to lunch on August 6th is £3 10*s.* inclusive, or 12*s.* 6*d.* per diem for those who stay for shorter periods. All communications should be addressed to Carteret House, S.W.1.

MEASUREMENT OF ALLERGY IN TUBERCULOSIS

ALMOST 45 years ago Robert Koch observed that tubercle bacilli injected into a healthy guinea-pig produced results very different from those obtained when the bacilli are injected into a tuberculous animal. He followed this up by further experiments which showed that dead tubercle bacilli or bacillary products (which he afterwards termed tuberculin) acted in the same manner as the living bacilli. He did not give a name to this phenomenon, but seven years later Clemens v. Pirquet, following his classical study of vaccinia, called it "allergy." All the years which have elapsed since Pirquet suggested that the reaction was allergic have not been sufficient to exhaust the discussion which has arisen as to the significance of the reaction to tuberculin in the diagnosis of tuberculosis. Even to-day, while it is agreed that a reaction is evidence of sensitivity to tuberculous infection, there is no agreement as to the quantitative value of the test, nor as to whether it may be taken as an index of immunity. Thus we have been driven to assume that there is what may be called a "general population" reaction, but are left in the dark about whether there is a definite relationship between the presence and intensity of the reaction and the clinical process. Rich, Jennings, Rothschild, and others[1] have shown that desensitisation may be produced without interfering with immunity. In a lecture delivered in March, 1934, at the Lister Institute of Preventive Medicine, and later elaborated in four papers[2] by himself and Dr. A. V. Chwalibogowski, Dr. Fr. v. Gröer, professor of pædiatrics in the University of Lemberg (Poland), has taken up the task of coördinating the facts about allergy. He regards allergy as a dynamic concept determined by two variable factors: susceptibility (S) and reactivity (R), which are in complex relationship to one another. The allergic process can be represented as a function of the factors S and R.

Applying the intradermal tuberculin test in falling decimal dilutions, and measuring in millimetres the diameters of the resulting skin reactions, he found it possible to differentiate three distinct groups of cases, according to the behaviour of the skin response as the concentration of tuberculin fell. In Group I. the diameters (D) were inversely proportional to the negative index of the concentration, so that the product ($D \times -\log C$) remained practically constant (homodynamic allergy, interpreted as signifying an exact balance between reactivity and susceptibility, $S = R$). In Group II. the diameters do not decrease proportionally with the concentrations, so that the product ($D \times -\log C$) progressively increases (heterodynamic allergy of "pleoræsthetic" type, $S > R$); while in Group III. the diameters fall rather precipitately as the concentrations fall, so that the product ($D \times -\log C$) progressively falls (heterodynamic allergy of "pleoergic" type, $R > S$). Methods are given for obtaining values of R and S from the allergy curves.

Correlation of the clinical groupings with these numerical data, oft repeated throughout long periods of observation, led to the following findings. Clinical Group I. (tuberculin-positive, no specific symptoms) belonged without exception to the pleoergic type. Clinical Group II. (suspects without definite symptoms, or cases which have recently shown some signs of active tuberculosis but actually free) exhibited the homodynamic, while Clinical Group III. (manifest tuberculosis with tendency to amelioration and recovery) and Clinical Group IV. (clinically bad prognosis) exhibited the pleoræsthetic type of allergy. These two latter groups could be distinguished only by repeated estimations of R and S, which indicated in the one case a transition from the pleoræsthetic to the homodynamic or pleoergic, and in the other a still further progress towards the pleoræsthetic state of allergy.

The conspicuous advantage of Prof. Fr. v. Gröer's formula lies in the fact that it reduces two variables to one numerical product, thus avoiding the mental correlation of dose with reaction. Unfortunately, so far as his experiments show, these results are only reliable in children, although he is engaged on work which he hopes may lead to an equally exact system of measuring sensitivity in relation to clinical activity for adults. The theory has been worked out in 100 children, and Gröer remarks: "The full significance of the method would be apparent on following up the alteration of the allergic condition over a period of clinical observation. *It is not the statics, but the dynamics of allergy that is of prognostic value.*" He admits the necessity for assessing sensitivity in conjunction with clinical observation, particularly in relation to the blood picture and the sedimentation-rate of the erythrocytes. While claiming that his is the only system which will furnish this "measure" of clinical condition or its absence, he recalls the attempt of Ellerman and Erlandsen in 1909 to solve the same difficulties. Gröer's quantitative methods and their bearing on diagnosis and prognosis deserve, in our opinion, the careful consideration not only of tuberculosis specialists but also of all engaged in the study of allergic disease.

RADIOGRAPHY UPSIDE DOWN

CHANGES in the radiographic appearance of the lung when the patient is (so to speak) standing on his head are reported by C. Malpelli,[1] who thinks inversion of value in the diagnosis of pulmonary lesions. In the usual upright position, the lung tissue is distended by its own weight and this distension is greatest at the apex. In the inverted position, the relative opacity of the apex and base of the lung is altered, the former becoming more and the latter less opaque; at the same time the general distension of the organ is reduced, since its weight exerts traction chiefly on the diaphragm, which is elastic and deformable, instead of on the relatively rigid chest wall. Malpelli discusses the information obtainable chiefly in relation to the presence, extent, and stage of tuberculous lesions. A small exudative focus which escapes recognition in films taken in the normal position may, he holds, be revealed by inversion, the reason being that factors which make for increased opacity at the inverted apex are especially active in the diseased area. When collapse therapy is under consideration and the discovery of any disease in the contralateral lung is important, the method is said to be definitely helpful. An obvious objection is that the patient is obliged to be in an uncomfortable position when the pictures are taken, and it is doubtful if this would be practicable in any but the mildest cases.

TREATMENT OF INGROWING TOENAIL

INGROWING toenail is one of those minor lesions that may lead to much trouble. After radical treatment by removal of nail and nail-bed the process of recovery may necessitate months off work, and involve no little discomfort. Among the causes H. S. Dolan[1] refers to trimming of the nails so that the corners are cut away; wearing of shoes that crowd the toes together; infection of the tissue adjacent to the side of the nail, which is already subjected to pressure and is unprotected where the nail has been pared; and (occasionally) trauma to the nail-bed, leading to deformity of the nail and its irregular growth. In the milder cases a cure may be wrought by getting the patient to wear the right shoes and cut the nails properly, steps being taken at the same time to harden and disinfect the granulating surface. For this last purpose Dolan advises that a small pad of absorbent cotton-wool soaked in tinct. ferri perchlor. should be worked in with a fine instrument beside the lateral margin of the nail, the process being repeated in two days' time. Where the infection is more severe, and the granulation tissue is heaped up over the margin of the nail, more drastic treatment is called for. Except in cases showing gross deformity and much pressure of the nail edges into the soft parts, Dolan does not advise complete eradication of the nail and nail-bed, preferring partial lateral removal of the nail and underlying bed, with removal of the granulation tissue at its edges. He operates with a tourniquet applied to the toe, and carries the incision downwards almost to the interphalangeal joint capsule of the distal joint. The healthy tissue outside the granulating area is undercut sufficiently to form a flap, and this is used to cover the raw surface left after excision of the strip of nail and nail-bed. Where complete removal of nail and nail-bed is required Dolan has been concerned to find a means of hastening the healing process, both because of the inconvenience and loss of time it involves, and because the slowly granulating surface is unpleasantly liable to infection, with a risk of osteomyelitis of the terminal phalanx. He does not altogether approve of the partial removal of the terminal phalanx, which was designed to allow the fleshy pad at the end of the toe to be sutured over the raw area. The disadvantages are that the end of the toe is left tender, and the toe is shortened. Dolan's plan is to do a more complete operation, dissecting up a flap over the base of the nail to ensure complete removal of all nail tissues; he then implants into the raw area a series of "pinch" skin-grafts, placed close together and lying on the periosteum. A layer of dry gauze holds the grafts in place, and outside this the toe is dressed with a thick layer of gauze soaked in paraffin. The operation is assisted by the use of a tourniquet. The patient returns for dressing on the day after operation, and is free of all discomfort after the second or third dressing. The gauze over the grafts is removed in 8–10 days, by which time the grafts have taken, and return to work is possible about a fortnight after operation. Dolan warns his readers against using local anæsthesia and a tourniquet in cases with definite infection. He thinks gas-and-oxygen is much safer, for injection of an analgesic may infect lymphatic channels, while the combined use of adrenaline and a tourniquet may lead to local sloughing.

KITCHENER SCHOLARSHIPS

THIS year 878 applications, representing 496 schools, were received by the scholarships committee, over which Sir James Currie presides, of the Lord Kitchener National Memorial Fund. Their task is to select from candidates, all of whom must be sons of officers and men who have served in H.M. Forces, those who show evidence of exceptional ability and have submitted a well thought out and precisely worded plan of training. The service of the applicant's father and the financial circumstances of his family are taken into consideration in the award of the scholarships, their value depending on the resources already available. Candidates must be over 17 and under 20 years of age, and the advanced course of training contemplated may be for industrial, commercial, or professional careers. The list of 145 successful candidates issued on May 20th contains the names of at least 16 young men who have chosen a medical training from those open to them at approved universities or institutions of university rank. We say at least, for it is possible that some of those who are proceeding to Oxford, Cambridge, or other universities may intend to study medicine there.

In addition to the 145 Kitchener Memorial Scholarships which carry no pledge of adherence to any particular branch of a profession, are the newly established Kitchener Medical Services Scholarships. Five of these have been awarded this year, two for the medical branch of the Royal Navy, two for the Royal Army Medical Corps, and one for the medical branch of the Royal Air Force. These scholarships are granted on condition that the scholar, on becoming qualified to practise medicine and surgery, will apply *forthwith* (our italics) for a regular commission in one of the Services and will render not less than five years' actual service on full pay. The Services reserve the right to deduct at their discretion the value of his scholarship from[1] any gratuity payable to a medical officer who fails to complete 15 years' service. Those who doubt whether it is justifiable to exact a pledge from a boy before he starts his medical studies to adopt a particular branch of medicine as a career will be relieved to learn that a refund of the scholarship money will release him from all obligations. The only criticism which we would offer concerns the word "forthwith" italicised above. We understand, however, that the interpretation of this word is in practice broad enough to allow a scholar the benefit of a resident hospital appointment.

VICTOR MORAX

Dr. Victor Morax, whose death occurred on May 14th in Paris, was an ophthalmologist, well known far away from Paris. He was born on the banks of the Lake of Geneva, but his medical education was carried out entirely in Paris and his first studies in bacteriology were carried out in that city. In 1900 he made an official visit to Egypt, and in the following year appeared his first significant contribution to the study of trachoma, the disease on which he was later to become the prime authority. Here he showed that many of the prominent symptoms were due to superimposed infections like the gonococcus and the pneumococcus, observations which led to the clinical division of trachoma into the chronic and the acute forms. For the next quarter of a century Morax held an important official post as clinical director at the Hôpital Lariboisière and he continued there his bacteriological studies, out of which sprang the French association entitled "The League against Trachoma." This society organised the publication of a journal dealing with trachoma, summarising all important contributions on the subject made in other languages. For the last ten years this journal has appeared quarterly under the title of "La Revue Internationale du Trachome," while Morax became a member of the executive committee of an international organisation against the spread of trachoma and was an important participant in all its activities. Latterly Morax had worked at the Pasteur Institute, with which he had always been in close touch, while 30 years ago he contributed to the Annales de l'Institut the discovery of the organism known as the Morax Axenfeld diplo-bacillus. As a member of the Ophthalmological Society of the United Kingdom, he delivered the Bowman lecture in 1919 at the annual congress of the Society held in London, his subject being plastic operations in the orbital region with special reference to war wounds, when he described in detail the methods chiefly directed to such repairs of the injured tissues as could be made for cosmetic purposes. He also wrote an admirable text-book on ophthalmology, and a treatise on the bacteriology of conjunctivitis, and was a regular contributor to the *Bulletins de la Société Française d'Ophtalmologie*. To the International Congress of Ophthalmology, held in Madrid in 1933, he submitted an important report on the ætiology of trachoma, and in the month of his death the *Annales de l'Institut Pasteur* contained an exhaustive review from him upon intraocular inoculation by tuberculosis bacilli. He was both a great worker and a great man of science.

A MEDICAL VICE-CHANCELLOR

THE appointment as vice-chancellor to a university of a graduate who has been associated with its activities almost continuously for nearly 30 years is a tribute to proved merit. On the scientific side Prof. J. S. B. Stopford, F.R.S., has served the University of Manchester as professor of anatomy since 1919, having previously been lecturer and before that demonstrator; his contributions to the anatomy of the living, dealing chiefly with sensation, the sensory pathway and the blood-supply of the brain, have brought fame to his alma mater as well as to himself. The development of his department at Manchester has made the subject of anatomy a vital part of the students' medical studies. On the academic side he has shown judgment and tact as dean of the medical school and pro-vice-chancellor of the university. His promotion at the early age o 46 to a position of high dignity will be regrette only by those who deplore the loss to neurolog which even a partial withdrawal of his energies fron active research must imply. Prof. Stopford has bee a prominent member of the General Medical Counc for many years and has shown keen interest in th knotty problems of the medical curriculum.

VIENNA GENERAL SPITAL

THIS week with the help of many foreign guest every medical faculty and every medical society i Vienna is celebrating the 150th anniversary of th foundation of the Allgemeines Krankenhaus whic has been identified as no other hospital in Europ with the teaching of clinical medicine. The foundatio of the General Spital, as it was then known, was th act of that enlightened Hapsburg monarch, Joseph II. and in its earliest days the hospital was directe by Johann Peter Frank, who, realising that clinica teaching must be controlled by the study of pathological anatomy, appointed the first prosector to a teaching school. In a festival number of the *Wiene klinische Wochenschrift*, Prof. Wagner-Jauregg eulogises this medical statesman and Prof. Max Neuburge tells the story of the school up to its culminatio at the beginning of the present century. Despit the levelling out of medical knowledge and practic the Vienna school is still making its contribution t medical thought and Neuburger finds a Vienn "nuance" in the theory and practice of all branche of medical science. The week ends with an addres by Prof. Paul Clairmont of Zurich, one of the surgica technicians of our time, on the way Vienna surgery has permeated the surgical schools of the world The festival number is evidence of the continuing liveliness of a school for which medicine everywher has respect.

THE Lister medal for 1936 has been awarded to Sir Robert Muir, F.R.S., professor of pathology in the University of Glasgow, and he will deliver the Lister memorial lecture at the Royal College of Surgeons of England next year. This is the fifth occasion of the award, which is made by a committee representative of the Royal Society, the Royal College of Surgeons of England, the Royal College of Surgeons in Ireland, the University of Edinburgh, and the University of Glasgow in recognition of distinguished contributions to surgical science. It may be noted that it is now exactly 75 years since Lister was appointed to the chair of surgery at Glasgow.

THE People's League of Health is appointing a committee to study the influence of diet on the health of pregnant women and the relation of nutrition to maternal mortality and morbidity. It is hoped to make a thorough and wide investigation and to publish a report in due course. The office of the League is at 12, Stratford-place, London, W.1.

THE trustees of the Rockefeller Foundation have promised to give £60,000 towards the building and equipment of the proposed institute for the teaching and study of neurology at the National Hospital, Queen-square, and a further £60,000 towards the endowment of the teaching and research that will be carried on there.

COUNTY HOSPITAL, EDMONTON.—The Middlesex county council has approved in principle proposals which, it is estimated, will cost about £500,000, for modernising this hospital and for adapting Edmonton House for hospital purposes.

PROGNOSIS

A Series of Signed Articles contributed by invitation

LIII.—PROGNOSIS IN OCULAR PALSY

THE term "ocular palsy" is used to express a condition of paralysis or paresis of one or more of the muscles which govern the movements of one eye; with these muscles may be associated the levator palpebræ superior, and the intra-ocular muscles of pupillary constriction and of accommodation.

Ocular palsy is due without exception to an organic lesion of nerve or muscle and its prognosis depends primarily upon the nature of that lesion and secondarily upon the age and recuperative power of the individual concerned; the length of time since the symptoms first appeared is also a factor.

SYMPTOMS

It is impossible to discuss this subject without some reference to its associated symptoms and also to the commoner of the causes which give rise to the condition. The chief symptom complained of by sufferers from pronounced ocular palsy is diplopia when an attempt is made to move the eye in the direction of the paralysed muscle, but in cases of mere muscular weakness patients may be unconscious of actual diplopia and may complain merely of confused vision and perhaps only of occasional giddiness. Indeed, patients complaining of giddiness should be tested for a possible ocular paresis; this especially applies to those giving a history of a head injury, and to all middle-aged and elderly people. If the internal ocular muscles are involved the pupil will be dilated and accommodative power weakened—the latter of course only in patients young enough to possess such power. A weakness of a depressor muscle is always more trying than that of lateral or elevator muscles owing to the confusion caused by looking down when walking. All varieties of muscular weakness are apt to be more pronounced when the patient's vitality is lowered, either by fatigue or illness.

CAUSATION AS IT AFFECTS PROGNOSIS

Traumatism.—In most cases the lesion is primarily a nervous one, although limitation of movement of an eye may be due to direct injury to the muscle itself, for example, by forceps bruising the external rectus in cases of difficult labour and by injuries to ocular muscles owing to perforation of the orbit by a sharp object. The prognosis in this type of direct traumatism is, as a rule, bad; the muscle does not usually recover from the injury and the development of scar tissue in cases of perforation may further impede movement.

A different type of traumatic paralysis is that which arises from head injuries, a variety only too common in these days of motor accidents. In cases of fracture of the base of the skull, one or more nerves supplying the ocular muscles may be torn across, in which circumstance complete paralysis occurs and no recovery is possible. But more frequently the muscle or muscles are not completely paralysed and gradual improvement takes place, the lesion being most probably a hæmorrhage into a nerve sheath; as the blood absorbs muscular power increases. So long as any improvement is taking place further amelioration may be hoped for, but when the condition has remained stationary for a time, say, two or three months, a return to normal is improbable.

Syphilis.—Ocular paralysis is frequently syphilitic in origin; here the prognosis depends partly upon whether the lesion is meningeal or intraneural. Meningeal gummata, which exercise pressure upon the nerves and are often multiple, react readily to antisyphilitic treatment and the diplopia is rapidly cured. Paralysis of the ocular muscles in tabetic cases may assume one of two forms: (1) a transient muscular weakness lasting a few days or weeks and gradually passing away; (2) permanent paralysis, complete or incomplete, of a single nerve or part of a nerve. Either form may occur at any stage, but the first is more common in the early and the second in the later stages of the disease. In my experience, however, permanent paralysis is the more common. From a prognostic point of view in syphilitic cases the presence of an Argyll Robertson pupil, in addition to the muscular weakness, is unfavourable, while a normal pupillary reaction augurs successful results from treatment.

The ocular paralysis of *disseminated sclerosis* is usually a transient one. In this disease the myelin sheaths of the nerve-fibres are the main object of attack, the axis-cylinders often escaping permanent damage. The prognosis of this type of ocular palsy is therefore good as a rule, complete recovery often resulting.

Ocular palsy may occur as a complication of *arterio-sclerosis and high blood pressure*, the slighter degrees of paresis giving rise to symptoms of giddiness and confusion, the greater to actual diplopia. Some improvement nearly always takes place; indeed, in my experience, most of these palsies are quite transient, disappearing gradually in the course of a few weeks. In few cases, however, a certain degree of permanent weakness is left. The actual nature of the lesion in these cases is somewhat obscure; most probably a small hæmorrhage has taken place in the neighbourhood of one of the motor nuclei. Although the prognosis as regards immediate improvement and ultimate recovery of movement is good, the outlook as regards life is bad, for a cerebral hæmorrhage may follow fairly closely on the heels of the ocular palsy.

The first symptom complained of by a patient with a *cerebral tumour* may be double vision, usually due, I think, to external rectus weakness owing to downward pressure of the brain on the sixth nerve; this is, of course, relieved by a decompression operation.

In cases of ocular palsies due to *toxic causes,* such as those complicating diphtheria and diabetes, the prognosis is good. A similar type of palsy is that following febrile diseases such as influenza and pneumonia; in these the prognosis is uniformly good. Mineral poisons, such as lead, may also affect the ocular muscles, these paralyses usually disappearing with the removal of the cause.

A somewhat disconcerting variety of ocular palsy is the *sixth nerve paralysis* occasionally met with as a sequel to a mastoid operation: in my experience the muscular weakness eventually disappears completely.

Encephalitis lethargica and *polio-encephalitis* are often complicated by ophthalmoplegia in the acute stages; in both of these conditions it is rare for the ocular muscles to remain permanently paralysed.

A certain number of cases of ocular palsy occur in which no general disease can be found and the lesion is extremely difficult to account for. These cases, which bear a resemblance to Bell's palsy, are usually ascribed to rheumatic neuritis of a motor nerve, but whatever the cause may be the prognosis of these *idiopathic* cases is uniformly good, the muscular

VICTOR MORAX

Dr. Victor Morax, whose death occurred on May 14th in Paris, was an ophthalmologist, well known far away from Paris. He was born on the banks of the Lake of Geneva, but his medical education was carried out entirely in Paris and his first studies in bacteriology were carried out in that city. In 1900 he made an official visit to Egypt, and in the following year appeared his first significant contribution to the study of trachoma, the disease on which he was later to become the prime authority. Here he showed that many of the prominent symptoms were due to superimposed infections like the gonococcus and the pneumococcus, observations which led to the clinical division of trachoma into the chronic and the acute forms. For the next quarter of a century Morax held an important official post as clinical director at the Hôpital Lariboisière and he continued there his bacteriological studies, out of which sprang the French association entitled "The League against Trachoma." This society organised the publication of a journal dealing with trachoma, summarising all important contributions on the subject made in other languages. For the last ten years this journal has appeared quarterly under the title of "La Revue Internationale du Trachome," while Morax became a member of the executive committee of an international organisation against the spread of trachoma and was an important participant in all its activities. Latterly Morax had worked at the Pasteur Institute, with which he had always been in close touch, while 30 years ago he contributed to the Annales de l'Institut the discovery of the organism known as the Morax Axenfeld diplo-bacillus. As a member of the Ophthalmological Society of the United Kingdom, he delivered the Bowman lecture in 1919 at the annual congress of the Society held in London, his subject being plastic operations in the orbital region with special reference to war wounds, when he described in detail the methods chiefly directed to such repairs of the injured tissues as could be made for cosmetic purposes. He also wrote an admirable text-book on ophthalmology, and a treatise on the bacteriology of conjunctivitis, and was a regular contributor to the *Bulletins de la Société Française d'Ophtalmologie.* To the International Congress of Ophthalmology, held in Madrid in 1933, he submitted an important report on the ætiology of trachoma, and in the month of his death the *Annales de l'Institut Pasteur* contained an exhaustive review from him upon intraocular inoculation by tuberculosis bacilli. He was both a great worker and a great man of science.

A MEDICAL VICE-CHANCELLOR

THE appointment as vice-chancellor to a university of a graduate who has been associated with its activities almost continuously for nearly 30 years is a tribute to proved merit. On the scientific side Prof. J. S. B. Stopford, F.R.S., has served the University of Manchester as professor of anatomy since 1919, having previously been lecturer and before that demonstrator; his contributions to the anatomy of the living, dealing chiefly with sensation, the sensory pathway and the blood-supply of the brain, have brought fame to his alma mater as well as to himself. The development of his department at Manchester has made the subject of anatomy a vital part of the students' medical studies. On the academic side he has shown judgment and tact as dean of the medical school and pro-vice-chancellor of the university. His promotion at the early age of 46 to a position of high dignity will be regretted only by those who deplore the loss to neurology which even a partial withdrawal of his energies from active research must imply. Prof. Stopford has been a prominent member of the General Medical Council for many years and has shown keen interest in the knotty problems of the medical curriculum.

VIENNA GENERAL SPITAL

THIS week with the help of many foreign guests every medical faculty and every medical society in Vienna is celebrating the 150th anniversary of the foundation of the Allgemeines Krankenhaus which has been identified as no other hospital in Europe with the teaching of clinical medicine. The foundation of the General Spital, as it was then known, was the act of that enlightened Hapsburg monarch, Joseph II., and in its earliest days the hospital was directed by Johann Peter Frank, who, realising that clinical teaching must be controlled by the study of pathological anatomy, appointed the first prosector to a teaching school. In a festival number of the *Wiener klinische Wochenschrift,* Prof. Wagner-Jauregg eulogises this medical statesman and Prof. Max Neuburger tells the story of the school up to its culmination at the beginning of the present century. Despite the levelling out of medical knowledge and practice the Vienna school is still making its contribution to medical thought and Neuburger finds a Vienna "nuance" in the theory and practice of all branches of medical science. The week ends with an address by Prof. Paul Clairmont of Zurich, one of the surgical technicians of our time, on the way Vienna surgery has permeated the surgical schools of the world. The festival number is evidence of the continuing liveliness of a school for which medicine everywhere has respect.

THE Lister medal for 1936 has been awarded to Sir Robert Muir, F.R.S., professor of pathology in the University of Glasgow, and he will deliver the Lister memorial lecture at the Royal College of Surgeons of England next year. This is the fifth occasion of the award, which is made by a committee representative of the Royal Society, the Royal College of Surgeons of England, the Royal College of Surgeons in Ireland, the University of Edinburgh, and the University of Glasgow in recognition of distinguished contributions to surgical science. THE MURUTS OF NORTH BORNEO

MALARIA AND RACIAL EXTINCTION

BY A. J. COPELAND, M.D. Camb., B.Sc. Glasg., D.P.H.

LATE GOVERNMENT DISTRICT SURGEON, BEAUFORT AND INTERIOR,
BRITISH NORTH BORNEO; FORMERLY ASSISTANT TO
THE DOWNING PROFESSOR OF MEDICINE,
UNIVERSITY OF CAMBRIDGE

THE Muruts of Borneo were formerly called "head-hunters" because they raided each other's villages to secure their enemies' heads, which were brought back, smoked, and hung up amongst the rafters of their large communal houses. This is an affair of the past, and under wise guidance by European district officers they have become a docile friendly people, intelligent and active, and well under the control of their headmen. But whereas their neighbours, the Dusuns, most of whom live at higher altitudes and in a more open environment, are largely on the increase, the Murut population *has been steadily falling during the past* eight years.[1] Dirt-borne diseases such as hookworm and amœbic dysentery, and infectious diseases such as influenza and measles, are equally common among the two races, but for the Muruts these are only last straws to break the camel's back. Their debilitated physique is everywhere associated with highly endemic latent malaria, and there is reason to think that, unless action is taken soon, this disease will soon make them as scarce as the wild Sakais of the remoter jungle districts of Malaya.

In North Borneo the Dusuns and Muruts represent the two ancient types of peoples, that is, the husbandmen and the hunters (Keith). The Dusuns live in upland plains and jungle country in the north as farmers, growing *padi* and breeding oxen and native buffaloes; they discontinued head hunting about fifty years ago. The Muruts, on the other hand, are hunters, living in the unhealthier dense jungle country in the south. They live by spearing and trapping deer, pig, and other jungle animals, by fishing in the rivers, and by raising small root and rice crops. The former number (1931 Census) 28,303 persons, the latter 21,903. There are also 3735 natives of mixed Dusun and Murut descent (the Kwijaus, around Keningau), and 2147 Chinese.

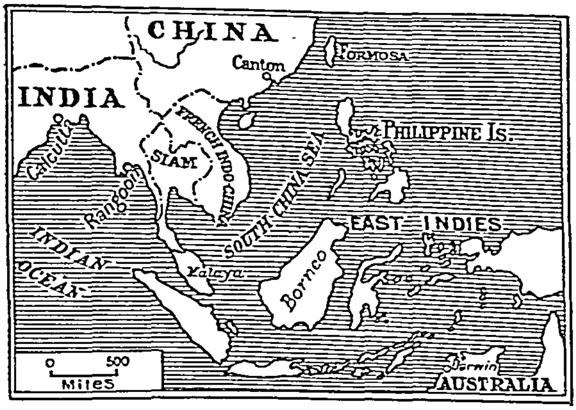

FIG. 1.—The geographical relations of Borneo.

These peoples live in primitive bamboo houses roofed with native thatch or *attap*. The Dusun house is much to be preferred to the Murut type; the former is just sufficiently large for one family, and each Dusun village has many small houses. The Murut house, on the other hand, is an enormous rambling bamboo structure in which dwells, not merely a family, but the entire village (Fig. 3). This dark and gloomy dwelling is supported on posts which are resting places for anopheles mosquitoes.

Medical Work in the Interior

In January, 1933, when I took charge as district surgeon, stationed at Tenom, the medical staff consisted of six dressers. These were responsible for the medical treatment of a population of some 56,000 persons. The skeleton medical service is based on six dispensaries, three for Dusuns and three for the Muruts. Of these, Tenom is now by far the best equipped (Fig. 4).

One of the pioneers of medicine in the interior was a young dresser named Mohammed Yusoph bin Samsudin, and an idea of the difficulties encountered may be gained from the following description of his experiences:

> "When I was first transferred from the Coast Hospital and take charge over Tambunan Dispensary in 1921, on my first visit to a village I found mostly of the natives both sexes adults and children were in a frightful condition and dirty, their villages and dwellings were awfully bad, dirty, dampy, and very bad smell, their health and physique were very poor. . . .
>
> "On one occasion I was ordered by the District Officer to attend to a patient a Government Native Chief in Kampong Kituntul of Tambunan District. On my arrival to that Kampong I found the patient was seriously ill passing blood and mucous stools about 15 to 20 times in 24 hours, than I told him I am going to give you an 'Obat chuchuk' otherwise you will not be cured and you may die. That is Emetine Injection, which I thought of giving it to him, he means and says 'tabak' is a word to spear, so he refuse and says to me I will 'tabak' you first and then you can 'tabak' me, so I have to return back to the Dispensary, I only send him a bottle of mixture to stop his diarrhœa, I attend to him the next day at the same time I brought my Hypodermic Syringe and needle, on arrival to his house after a while I take out and show him the needle, then he said to me he thinks it was a big needle like one of his small spear and that is the reason why he refuse to accept the injection, after he have seen the needle than he allow me to give him the injection, but still he is doubtful, he calls his people to watch and see me while giving the injection to him and he says to his people

weakness disappearing after a variable interval of time.

Ocular palsy is associated with other *rarer nervous diseases*; in most of them the prognosis of the ocular lesion is bad; also the palsies associated with myasthenia gravis have a thoroughly bad prognosis. Quite recently it has been shown that the administration of Prostigmin causes temporary relief in myasthenic cases, but it is still too early to say whether more lasting results can be obtained.

DEGREE OF RELIEF BY LOCAL MEASURES

With regard to the question whether ocular paralysis can be alleviated by local measures, apart from the treatment of any general disease which may be their cause, the two conditions which call for treatment are (1) the diplopia, and (2) the unsightly appearance of squint caused by paralysis of a muscle.

(1) *Diplopia.*—The diplopia interfering with distant vision cannot be helped by means of prisms, as it is variable in amount, changing with every movement of the eyes. But on the contrary the distressing diplopia on reading, caused by the paralysis or weakness of a depressor muscle, can often be entirely relieved by the incorporation of a suitable prismatic correction in reading-glasses. The reason for this difference is that the vertical movement of the eyes when reading is a limited one, mainly lateral ocular movements taking place as the eyes move along the page.

(2) *Appearance.*—Operations undertaken to lessen the squint caused by a completely paralysed muscle are undoubtedly of value, especially in cases where a lateral muscle is affected. Careful tenotomy of the opposing muscle, with or without shortening of the paralysed one, will usually bring the eyes into line when they are looking straight forward.

When a diplopia remains persistent, patients often become less conscious of its presence, their discomfort or confusion becoming gradually less distressing. This is probably due to their learning to suppress the image seen by the paralysed eye; there is no doubt that young patients acquire the power of ignoring the second image more readily than older ones.

Complete paralysis of the third nerve, involving as it does ptosis and consequent covering of the eye by the paralysed lid, is the least worrying form of ocular palsy as far as the diplopia is concerned because the latter symptom is abolished by the closure of the lid.

R. AFFLECK GREEVES, F.R.C.S.,
Surgeon, Royal London Ophthalmic Hospital; Senior Ophthalmic Surgeon, Middlesex Hospital.

THE SERVICES

ROYAL NAVAL MEDICAL SERVICE

Surg. Comdr. J. E. Clarke to *Drake* for R.N.B.

Surg. Lt.-Comdrs. H. G. Wells and E. H. Rampling, and Surg. Lt. F. W. Chippindale to *Pembroke* for R.N.B.

Surg. Lt.-Comdr. R. W. Higgins to rank of Surg. Comdr.

Surg. Lt.-Comdr. (D.) W. E. A. Sampson, placed on the Retd. List, at own request, with rank of Surg. Comdr. (D.)

ROYAL NAVAL VOLUNTEER RESERVE

Surg. Lt.-Comdr. A. R. Thomas to *Tiverton*.

Surg. Lt. J. N. Matthews to *Pembroke* for R.N. Hospital, Chatham.

Proby. Surg. Lt. G. E. M. Benson to *Renown*.

Proby. Surg. Lt. C. J. T. Watson to be Surg. Lt.

ROYAL ARMY MEDICAL CORPS

Short Serv. Commissions.—Lt. (on prob.) P. L. E. Wood is restd. to the estabt. N. I. McLeod to be Lt. (on prob.).

SUPPLEMENTARY RESERVE OF OFFICERS

G. F. E. Ramsden to be Lt.

TERRITORIAL ARMY

Lt.-Col. E. W. Matthews, T.D., having attained t age-limit, retires and retains his rank, with permission wear the prescribed uniform.

R. H. Baker McCrae to be Lt.

A. Cowie (late Offr. Cadet, Aberdeen Univ. C (Med. Unit), Sen. Div., O.T.C.) to be Lt.

SHORT SERVICE COMMISSIONS IN THE R.A.M.

The following candidates have been granted sh service commissions as lieutenants on probation in t Royal Army Medical Corps:—B. d'E. Barclay, M Otago; N. I. McLeod, L.M.S. Queen's Univ., Ontar G. S. Musgrove, M.D. Manitoba; D. S. Cochran, M.B. Aberd.; P. R. Wheatley, M.B. Lond. (Guy's); N. Flaherty, M.B. N.U.I. (Cork); T. P. O'Brien, M.B. N.U.I. (Cork); M. Kosloff, M.R.C.S. (Guy's); J. M. Lockie, M.B. Edin.; J. J. Groome, M.B. N.U.I. (Dubl C. Ryan, M.B. Dub.; A. Gleave, M.B. Liverp.; J. L Gordon, M.R.C.S. (Middlesex); J. S. Kelleher, M.B. N.U.I. (Cork); W. B. Hamilton, M.B. Dub.; G. G Robertson, M.B. Edin.; A. M. Pugh, M.B. Glasg. J. H. Taylor, M.B. Glasg.; D. Wright, M.B. Glasg. A. C. Cox, M.R.C.S. (Guy's); D. N. Keys, M.B. Dur. G. C. Dansey-Browning, M.R.C.S. (St. Thomas's A. H. T. F. Fullerton, M.R.C.S. (Birmingham); and J. F Weir, M.B. Aberd.

ROYAL AIR FORCE

Group Capts. W. Tyrrell to Headquarters, R.A.F. Inland Area, for duty as Principal Medical Officer; F. C. Cowtan to Headquarters, R.A.F. Middle E Cairo, for duty as Principal Medical Officer, vice Gr Capt. W. Tyrrell.

Wing Comdrs. R. S. Overton to Headquarters, R.A.F. Iraq, for duty as Deputy Principal Medical Officer, v Wing Comdr. P. T. Rutherford; and E. A. Lumley Headquarters, A.D.G.B., Uxbridge, for duty as Princ Medical Officer (Hygiene), vice Wing Comdr. Montgomery.

Squadron Leaders E. C. K. H. Foreman to R.A.F. Hospital, Cranwell, for duty as Medical Officer; C. F. O'Neill, O.B.E., to No. 3 Flying Training School, Granth for duty as Medical Officer.

Flight Lts. P. D. Barling to R.A.F. General Hosp Hinaidi, Iraq; G. A. M. Knight to R.A.F. Hos Aden; G. M. Anderson to No. 1 Armament Tra Camp, Catfoss; and C. H. Smith to R.A.F. Ge Hospital, Palestine and Transjordan.

Flying Offrs. R. G. James to No. 3 Flying Tr School, Grantham, and G. H. Morley to Princess R.A.F. Hospital, Halton.

Flight Lt. J. D'Isney Rear is promoted to the r Squadron Leader.

INDIAN MEDICAL SERVICE

The provisional promotion of Maj. J. McM. is confirmed and antedated to March 28th, 1933.

PERMANENT COMMISSIONS IN THE I.M.S

The selection committee is meeting at the India in June to consider applications for permanent c sions in the Indian Medical Service from well-qual men of pure European descent (British subjects) un 32 years of age. The selected candidates will course of instruction in this country before sailing India in the autumn. Further particulars will be i in our advertisement columns.

ST. BARTHOLOMEW'S HOSPITAL, ROCHESTER.—Th income of this hospital has increased, but som £30,000 is still needed to complete the proposed exte sions, which include X ray therapy equipment. Th average cost per week for each in-patient was £2 17s. as against £2 19s. 6*d*. in the previous year. The numb of in-patients showed a slight increase and the number new out-patients a slight decrease.

dently, and with greater economy. The expeditions must be made at the time of year convenient to the natives—i.e., when they have least agricultural work. In the interior, June and November are the best months. I found it was not uncommon for a dresser to be unable to collect patients because the villagers were either engaged in husbandry or in communal drinking parties. For these occasions many jars of rice spirit or *tapei* are prepared, to be sucked up through hollow canes, the end-point for each pair of drinkers being the disappearance of a generous measure of water through holes in a large leaf. Muruts and Dusuns are so partial to this indulgence that all persons (excepting small children) partake in pairs in turn, day and night, until the supply is exhausted. Let the visitor, when he opens the party (as *adat* or native custom ordains), disregard the occasional passage of a bulky insect up through the tube; the polite words of thanks are, in Murut, *amis kepioh*—how deliciously sweet!

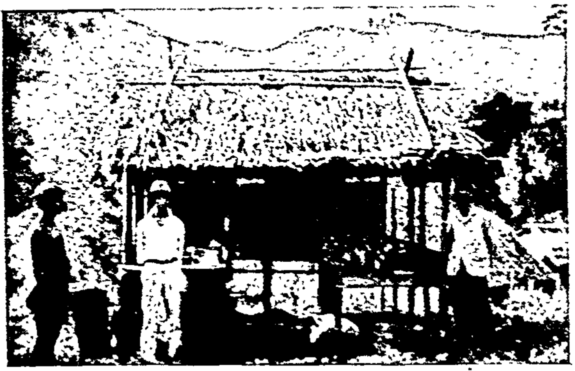

FIG. 5.—A small dispensary, with dressers and carrier.

The calendar in North Borneo is the knotted rattan fibre, one knot for each day. The headmen, on their return from the Government station, distribute these *timbuku* to their villagers, who cut off one knot a day. When only four or five knots are left, they come in to the treatment centre.

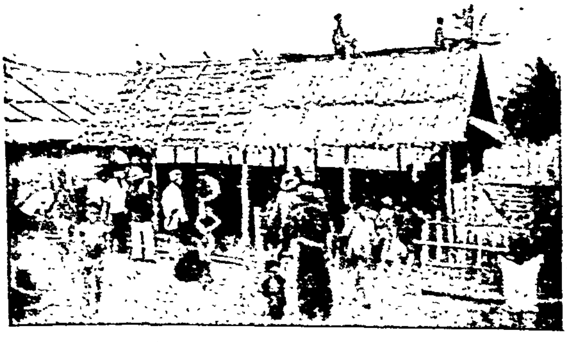

FIG. 6.—A large temporary dispensary in process of erection by Dusuns.

A medical examination, to the native, is only a tiresome and rather unnecessary preliminary to the giving of *obat*, *kapas*, and *ikat* (medicine, dressing, and bandage), but this depressing attitude is not confined to jungle folk. The necessary treatment must not, however, be delayed, lest the patient should exhaust his food supply—always carried on the person—before the trip is completed. Any examination (e.g., scientific tests such as blood groupings) which is not followed by treatment causes cruel disappointment to those who have travelled long journeys of many days, expecting medicines and dressings, and the matter is neither forgotten nor forgiven. For this reason, *any* purely scientific expedition amongst natives should always be accompanied by a dresser having local knowledge and equipped with sufficient medical supplies.

THE MEDICINE MARKET

Jungle dispensaries.—The natives are very skilful in the making of small houses of bamboo, roofed with leaves. Such a temporary *sulap* can be erected in half an hour (Fig. 5). The people willingly put up larger and more permanent places without cost, so anxious are they for treatment, and especially for quinine. The type of structure that was found to be most useful was as follows (Fig. 6):—

Length 36 ft., width 18 ft., open on one side; the whole surrounded by a fence to keep out crowds. No floor, and attap roof. Three sides carry a wide side platform, 4 ft. wide, at a convenient height. In the centre is a wide bamboo table 18 ft. by 9 ft. This forms a strongly built structure, useful for medical work, including the giving of large numbers of intravenous injections for yaws, and as a temporary rest-house for patients at night.

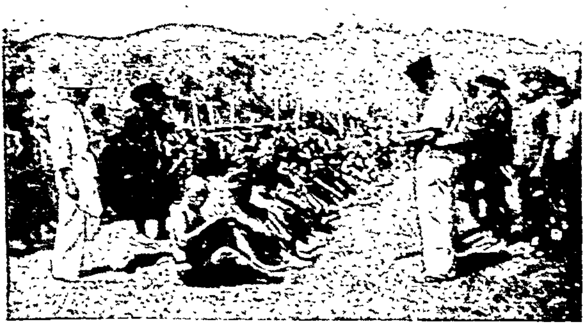

FIG. 7.—Waiting for the medical officer (Dusuns).

Examination of patients.—Men, women, and children were examined separately, grouped according to their villages. The method was for the natives to sit in a long line on the grass (Figs. 7 and 8). As the medical examiner approached they lay back, with the arms by the sides, and the knees drawn up. Spleen measurements were made by taking the distance in centimetres between the apex of the spleen and the costal margin. Patients whose symptoms or physical signs pointed to some complaint necessitating a further examination were noted down and seen later.

Records.—I devised a simple system which any dresser could make use of, working single-handed, and from which the spleen indices and other statistics could readily be calculated.

Temporary native treatment centre at ....
Date..............
Villages:
1. .... Headman ....
2. .... Headman ....
&c.

Adult males. Adult females.	Children, 2–10 years. Infants.
Spleen not enlarged.	*Spleen enlarged.*
Healthy. Yaws. Other diseases.	Malaria only. Yaws. Other diseases.
Names, &c.	Names, &c. ....

Dispensing.—Bottles (always scarce) were collected at the time of examination, and a coloured voucher if I die through the 'tabak' by the 'kerani' (dresser) that is the injection, all of you kill the 'kerani' too for me. . . .

"I came across to a wound case, I wanted to apply a few stitches, the patient refuse and said to me my skin is not a cloth, and how could you stitch it, I explained to him as regards to this matter, but still he refuse, and said I want 'Obat' medicine only, I can do it myself in the Kampong, so I gave him some dressing and off he went with the bleeding wound."

This intelligent dresser soon gained the confidence of the natives, and during the next 13 years, in addition to other excellent work in all parts of the interior, gave many thousands of intravenous novarsenobenzol injections for yaws. His special experience is now lost, as he has been removed to the Coast.

The next advance was made by Dr. G. G. Campbell, medical officer to Sapong Estate, when he initiated the successful yaws campaign.[1] The rapid action of N.A.B. in clearing up yaws lesions has given such confidence that many natives now demand an injection or *chuchuk* for all ailments.

MEDICAL SURVEY EXPEDITIONS

During 1933 I made five tours to many parts of the interior, accompanied by one or more dressers, with full medical equipment. In 106 days more than 3000 natives (Dusuns, Muruts, and Kwijaus) were examined and treated, medically and surgically. I was able to cover about 750 miles by pony, 250 miles on foot, and about 30 miles by native canoes. The statistical results obtained were fully confirmed by a more complete survey of 5423 natives in all parts of the Interior made during the first half of 1934 by six dressers. These workers, whose names are Mohammed Yusoph bin Samsudin, Mohammed Gani, Wong Boo Choon, Chin Hin Shing, Chin Yun En, and Andau bin Tangkim, travelled 2500 miles and visited 171 villages. Their detailed reports are far in advance of any field records previously made in North Borneo, and the work they accomplished is beyond praise.

FIG. 3.—The front of a typical Murut house.

In order to make the best use of the small and scattered staff, I gradually evolved a system of temporary native treatment centres which became so popular tha they came to be known as "medicine markets"—the *Tamu berobat*. It was found that two persons working together methodically to a time schedule, when their arrival had been expected, could accomplish more than three or four working indepen-

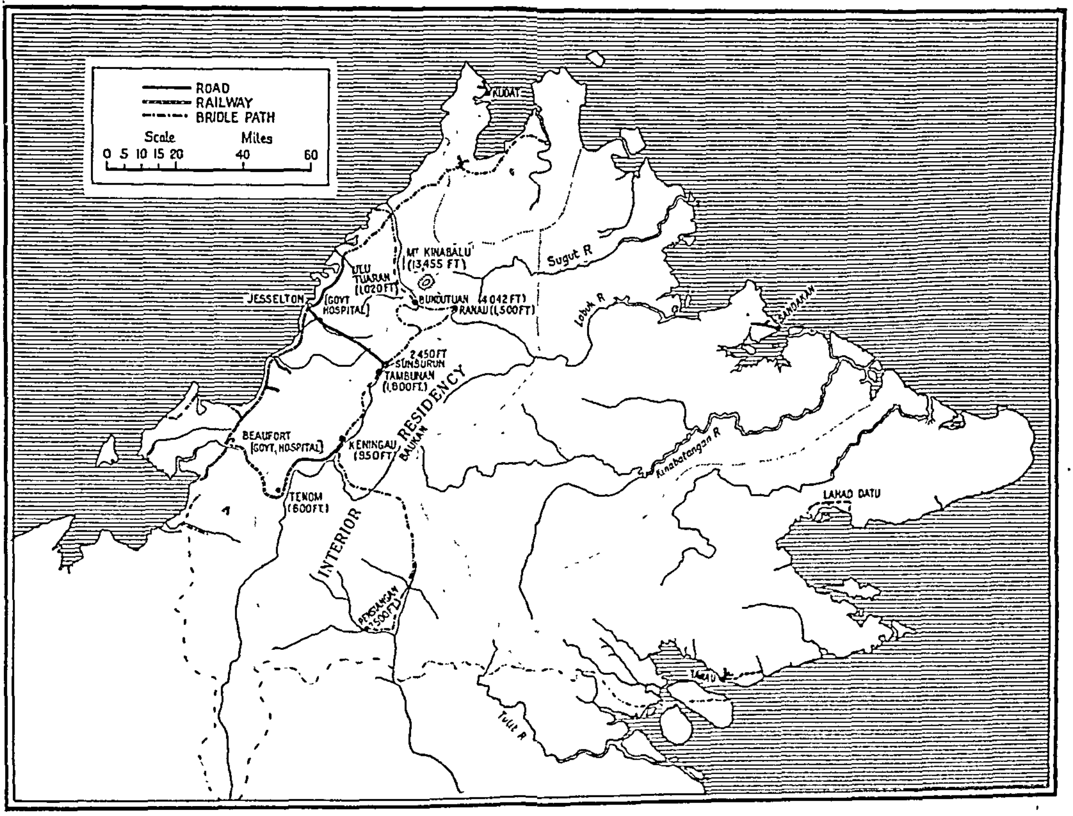

FIG. 4.—Map of British North Borneo, showing the position of the six dispensaries of the Interior Residency. Their height above sea level is indicated and their lines of communication.

dently, and with greater economy. The expeditions must be made at the time of year convenient to the natives—i.e., when they have least agricultural work. In the interior, June and November are the best months. I found it was not uncommon for a dresser to be unable to collect patients because the villagers were either engaged in husbandry or in communal drinking parties. For these occasions many jars of rice spirit or *tapei* are prepared, to be sucked up through hollow canes, the end-point for each pair of drinkers being the disappearance of a generous measure of water through holes in a large leaf. Muruts and Dusuns are so partial to this indulgence that all persons (excepting small children) partake in pairs in turn, day and night, until the supply is exhausted. Let the visitor, when he opens the party (as *adat* or native custom ordains), disregard the occasional passage of a bulky insect up through the tube; the polite words of thanks are, in Murut, *amis kepioh*—how deliciously sweet!

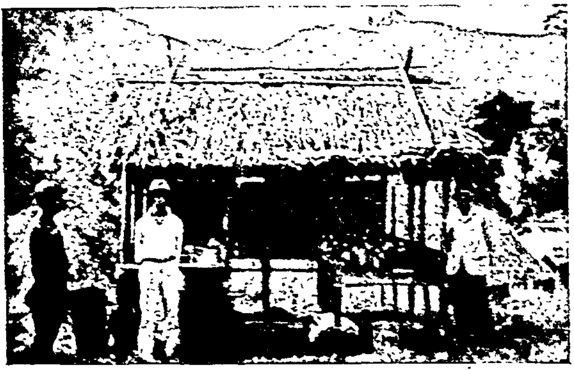

FIG. 5.—A small dispensary, with dressers and carrier.

The calendar in North Borneo is the knotted rattan fibre, one knot for each day. The headmen, on their return from the Government station, distribute these *timbuku* to their villagers, who cut off one knot a day. When only four or five knots are left, they come in to the treatment centre.

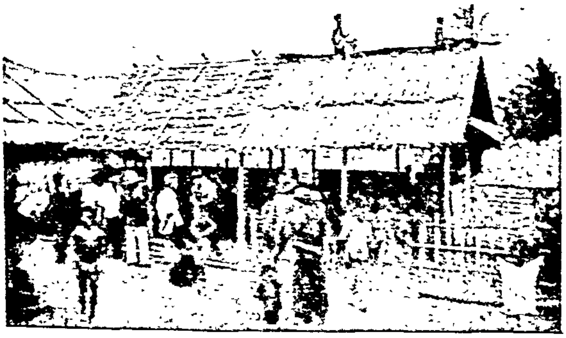

FIG. 6.—A large temporary dispensary in process of erection by Dusuns.

A medical examination, to the native, is only a tiresome and rather unnecessary preliminary to the giving of *obat*, *kapas*, and *ikat* (medicine, dressing, and bandage), but this depressing attitude is not confined to jungle folk. The necessary treatment must not, however, be delayed, lest the patient should exhaust his food supply—always carried on the person—before the trip is completed. Any examination (e.g., scientific tests such as blood groupings) which is not followed by treatment causes cruel disappointment to those who have travelled long journeys of many days, expecting medicines and dressings, and the matter is neither forgotten nor forgiven. For this reason, *any* purely scientific expedition amongst natives should always be accompanied by a dresser having local knowledge and equipped with sufficient medical supplies.

THE MEDICINE MARKET

Jungle dispensaries.—The natives are very skilful in the making of small houses of bamboo, roofed with leaves. Such a temporary *sulap* can be erected in half an hour (Fig. 5). The people willingly put up larger and more permanent places without cost, so anxious are they for treatment, and especially for quinine. The type of structure that was found to be most useful was as follows (Fig. 6):—

Length 36 ft., width 18 ft., open on one side; the whole surrounded by a fence to keep out crowds. No floor, and attap roof. Three sides carry a wide side platform, 4 ft. wide, at a convenient height. In the centre is a wide bamboo table 18 ft. by 9 ft. This forms a strongly built structure, useful for medical work, including the giving of large numbers of intravenous injections for yaws, and as a temporary rest-house for patients at night.

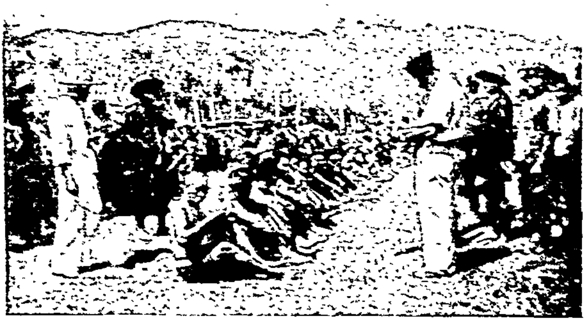

FIG. 7.—Waiting for the medical officer (Dusuns).

Examination of patients.—Men, women, and children were examined separately, grouped according to their villages. The method was for the natives to sit in a long line on the grass (Figs. 7 and 8). As the medical examiner approached they lay back, with the arms by the sides, and the knees drawn up. Spleen measurements were made by taking the distance in centimetres between the apex of the spleen and the costal margin. Patients whose symptoms or physical signs pointed to some complaint necessitating a further examination were noted down and seen later.

Records.—I devised a simple system which any dresser could make use of, working single-handed, and from which the spleen indices and other statistics could readily be calculated.

....

Dispensing.—Bottles (always scarce) were collected at the time of examination, and a coloured voucher was given in exchange. The bottles were grouped on the grass, and later removed to the sulap dispensary, where they were filled with the requisite mixture from concentrated stock after the first day's work. The bottles were held in position on the platform by strings of rattan, and patients were warned that persons causing these bottles to be spilt would acquire all the diseases which would otherwise have been cured! The bottles were kept back, for obvious reasons, until the completion of the hookworm treatment. The owners were then admitted a few at a time to receive medicines and dressings, and special treatments, such as the application of lint soaked in medicinal paraffin to dirty ulcers, castor oil locally for pink eye, and dental extractions. The women often file the front teeth for cosmetic effect, and the filed stumps decay and cause much trouble.

Schedule of work.—The following is typical of three days' work at a tamu berobat, or medicine market:—

First day.—12.30 P.M. to 6 P.M.: examine 80 men, 74 women, 87 children. Total, 241 persons.

Second day.—6.45 A.M. to 7.30 P.M.: examine 154 men, 132 women, 122 children (total, 408); 100 cases of yaws receive salts; 250 bottles of medicine dispensed.

Third day.—6 A.M. to 6.45 P.M.: 83 intravenous N.A.B. injections, and 7 Acetylarsan injections for yaws, after temperatures taken and urine boiled. Mass hookworm treatment for 167 men, 155 women and 120 children (total, 442). Salts at 7 A.M., oil of chenopodium at 9, 10 and 11 A.M. and salts again at 1 P.M. Gave out 250 bottles; treatments for ulcers, septic wounds, conjunctivitis, dermatitis, tinea, scabies, &c.

Fourth day.—Left Centre at 6.30 A.M.

Staff.—1 medical officer, 1 district officer, 1 dresser, 1 chief headman, 2 native policemen (total, 6).

A Vanishing Race

An official report dated Feb. 18th, 1932, states that, although the figures cannot be regarded as accurate, during each of the years 1927–31 the number of deaths registered in the four Murut districts considerable exceeded the number of births. In the Dusun districts the births exceeded the deaths in 1930 and 1931, and also in 1929 at Ranau. The birth- and death-rates (per 1000 of population) are shown in Table I.

The conclusion drawn was that the Murut population was steadily decreasing, whereas the Dusun population had increased since 1930.

Mr. A. F. Richards, late governor of British North Borneo, whose encouraging interest in the work done in the interior I gratefully acknowledge, in a note dated Feb. 22nd, 1932, pointed out that "the tendency of such primitive races to decrease is a problem by no means confined to the State. The best means of combating the causes that contribute to the decline in their numbers is the provision and extension of medical facilities." What is this recent mysterious "tendency to decrease" which the equally primitive Dusuns have escaped? As possible causes of the decrease, Mr. Richards referred to bad sanitation, birth control, alcohol, and dietetic deficiencies. In July, 1933, I was able to elicit the views of the native headmen of the Baukan Murut country, when I visited their villages, and the headmen informed me that, in their opinion,

(*a*) Children are noticeably fewer than ten years ago.

(*b*) There are fewer pregnant women. The reason for this was not clear to the chief headman, but he thought it was largely due to venereal disease.

(*c*) Women do not miscarry more than ten years ago, and the number of miscarriages is not great.

(*d*) *The married women want children,* and are very disappointed when they fail to achieve pregnancy. Contraception is not practised.

(*e*) They had never heard of abortion being procured.

(*f*) There are not more deaths in childbirth than there were ten years ago.

FIG. 8.—Examination of feet for crab yaws (Dusuns). Dresser on right.

TABLE I.—*Birth-rates and Death-rates in the Interior* (*per* 1000)

—	Estimated population on Dec. 31st, 1931.	Birth-rate for 1931.	Death-rate for 1931.

(*g*) The food supply is the same in quantity and variety *as it was ten years ago.*

(*h*) *There are more clearances of jungle than there were ten years ago.*

(*i*) *There are more cases of fever than there were ten years ago.*

I think that these last two statements contain the explanation of the "tendency to decrease."

Prevalence of Malaria

Campbell, in the report already mentioned, describes the malaria situation as follows:—

"On Estates during the years 1917 to 1925 the predominating type of Malaria was a mild Benign Tertian, with sporadic cases of Quartan and Subtertian. This was probably the type endemic to the country, and the type to which the Borneo native had developed a certain degree of immunity. With the great influx of Javanese in 1925–1927 *our type* of Malaria changed to a virulent and predominating Subtertian, disseminated by the new labourers, 65 per cent. of whom (even by the thin smear method) were found positive to Subtertian Malaria on arrival. The natives, as usual, journeyed down to the

Estates to find work, contracted this new and virulent type of Malaria to which no resistance had been developed, and when unable to work went home to spread it amongst their friends and relatives in the Kampongs (villages)."

The results of this change in infection are seen in the figures shown in Tables II. and III.

Predominant type of malarial parasite.[5]—The following are the results of 420 consecutive thick blood film examinations at Tenom in January to June, 1934—subtertian, 23·9 per cent.; benign tertian, 14·4 per cent.; quartan, 0·2 per cent.; mixed subtertian and benign tertian, 0·9 per cent.; negative, 60·6 per cent. The predominant malarial parasite amongst Muruts is *Plasmodium falciparum*.

Incidence of splenomegaly.—The findings set out in Tables II. to IV. have been submitted to the British North Borneo (Chartered) Company.[5] They refer to 5423 natives, of whom 1892 are Muruts and 3531 are Dusuns. There were also 500 Muruts in the Pensiangan Group II. area, but these are not included, since the records are no longer available. In regard to no fewer than 3877, including all the Muruts, the actual names of the natives and the names of their villages and headmen are recorded, together with further information as to spleen measurement and any other disease or diseases found.

* District Surgeon's Survey, 1933, before mass treatments for latent malaria, hookworm, &c., had been given in this group of villages (both from Sunsuron, 6 miles north of Tambunan).

Of those examined, 2914 of the natives of the interior, with Ulu Tuaran and Meridi—comprising 1082 Muruts and 1832 Dusuns—suffered from spleen enlargement, and most of them from other diseases too. I saw one Murut who had enlargement of the spleen due to latent malaria with coexistent yaws, balanitis and gonorrhœa, and helminthic disease. The association of helminthic disease with latent malaria is almost universal, and to this foundation is frequently added one or even several of the following: amœbic dysentery, hepatitis, liver abscess (sometimes enormous: from one Murut I removed 6 pints 12 ounces of "strawberry fool" pus at one evacuation, using a Potain's aspirator, and he went home on the fifth day); blindness in one or both eyes due to old gonorrhœal or tropical ophthalmia, yaws (now greatly diminished in incidence), goitre, rheumatism, bronchitis, ulcers, tinea imbricata, and, in many cases amongst the Muruts, gonorrhœa. A comfortable phrase such as "the tendency of such primitive races to decrease," written in all innocence, can sometimes cover a multitude of diseases. When I toured amongst the Muruts, I was astounded that humanity could survive such multiple infections and afflictions.

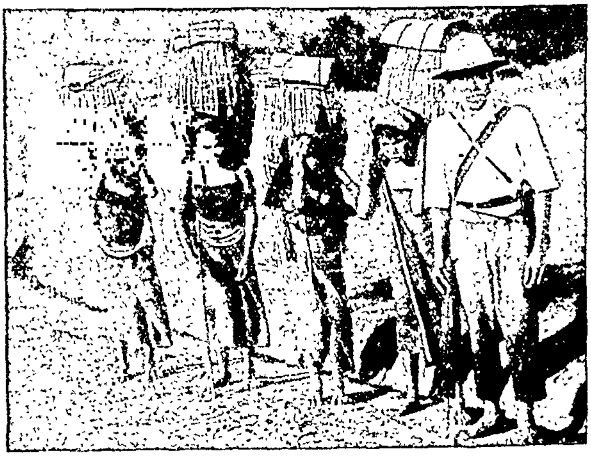
GENERAL CONSIDERATIONS

Quinine has been, and is doubtless still, distributed amongst the inhabitants of the interior. The amount provided, however, is such that one can only describe these people as *an untreated population.* The statistics summarised in Tables II. to IV. are of all the more interest because the 56,000 inhabitants are spread over some 6500 square miles comprising areas widely contrasted as regards country (jungle and open uplands), altitude (between 600 and 4042 ft.), native dwellings (large communal and small family), and types of native (hunters and husbandmen). Four main conclusions can be drawn :—

(*a*) Malaria is highly endemic amongst all the Muruts, but of low endemicity amongst the Dusuns, except the Ranau Dusuns, amongst whom it is hyperendemic.

(*b*) There are two types of district in the interior. In Type I. a high spleen index is associated with a high or even higher infant spleen index, and a high adult spleen index in which the adult female index is nearly equal to or sometimes higher than the adult male index. Type II., on the other hand, has a low spleen index, associated with a negative infant spleen index, but with an adult spleen index higher than the true spleen index. In this type the adult male spleen index is higher than the adult female spleen index. The exception is in the Ulu Tuaran, where the women work as tobacco carriers (Fig. 10), and travel further from home than the men. I suggest that in the first type the principal source of infection is in or close to the dwelling place, while in the second type the houses are less malarious. It is, of course, obvious that in an untreated community the distribution of malarial infection amongst groups of individuals living or working in close proximity to anopheles breeding places must bear some inverse ratio to the average number of "danger hours" passed in safe or safer zones, and the converse must also be equally true. By "danger hours" I mean the hours of feeding of the local female anopheles mosquitoes.



[*Photograph by Gaya*

FIG. 10.—Dusun women from upland districts carrying tobacco.

(*c*) The intensity of infection, estimated by the average spleen enlargement, appears to be greatest in the Tenom and Pensiangan districts—i.e., in the districts nearest to the rubber estates. This confirms Dr. Campbell's clinical findings.[1]

(*d*) The extremely low child population amongst the Muruts, and also amongst the Ranau Dusuns, is shown in Table IV. The scarcity of children was very noticeable in the Baukan country east of Keningau when I visited the villages. The Table suggests strongly that malaria is *the* vital factor in the causation of a low child population in the above areas. The figures are not exactly accurate, but give an idea of the comparatively low child populations in the worst malarious areas. They provide, in fact, ample evidence of the truth of Campbell's saying that the Muruts are "doomed to slow but inevitable extinction, unless given systematic and energetic medical aid."[1]

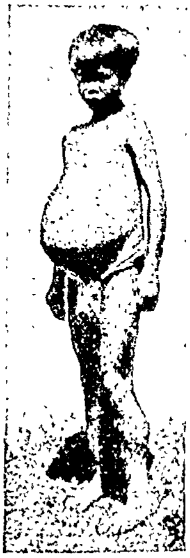


FIG. 11.—A Dusun boy with malarial splenomegaly.

In the tropics, when malarial infection becomes general in young children (Fig. 11), or when a virulent parasite is introduced, and becomes established, the situation needs at least as much attention as a dangerous epidemic receives in Europe.

WHAT IS BEING DONE

Apart from weekly antilarval oiling at Tenom and Keningau stations, the campaign against malaria is carried on entirely by the distribution of drugs from the six dispensaries. (Two of these have hospitals with 16 beds, and two others have rest-houses for patients.) Quinine sulphate is the remedy chiefly employed and gives satisfactory results administered as a powder in capsules. The quantities allotted in 1932, and during the first nine months of 1933, are shown in Table V.

In addition a small amount of quinine bihydrochloride and quinine ethylcarbonate (Euquinine) is available. The cost of quinine sulphate in North Borneo is approximately 37*s.* per pound; this is 680 ten-grain doses, and according to Bass[8] is sufficient for the disinfection of 10 adults when spread over eight weeks. On the basis of Bass's figures therefore the cost of disinfection for each adult is 3*s.* 8*d.* in North Borneo. To this must be added the cost of 15 tablets of Plasmoquine (1*s.* 2*d.*) for complete sterilisation, making a total of 4*s.* 10*d.* for the complete sterilisation of one adult. The cost of ridding 22,000 Muruts of malarial parasites would consequently be £5316; whereas the cost of the quinine actually supplied in 1932 to the three Murut districts, to a population of 27,252 (including Kwijans and 2147 Chinese), works out at £57 8s.

TABLE V.—*Quinine Sulphate (lb.) Allotted to North Borneo Natives* [3]

	1932.	1933 (9 months).
Murut districts (population 27,252) ..	31	17
Dusun districts (population 28,831) ..	36	22¼
Total (population 56,083)	67	39¼

Each adult male native pays a poll tax of 2*s.* 4*d.* per annum to the British North Borneo (Chartered) Company, in whose hands the government of the country rests. This company, the last of the chartered companies, is answerable to its shareholders in matters of finance. The poll tax is a hardship, as the Muruts have great difficulty in disposing of their jungle produce (rattan, resin, camphor, &c.) to the Chinese for cash instead of by the usual barter. The healthy looking cheerful aborigines of Australia have a monthly allowance of groceries, free blankets, and are exempt from taxation. The last privilege might be granted the

Muruts and Ranau Dusuns, in view of their extreme poverty and debilitated physical condition.

Conclusions

(1) The Murut race is steadily decreasing; it has a low birth-rate and a high death-rate. (2) Malaria is highly endemic amongst the Muruts, and hyper-endemic amongst the Ranau Dusuns, and the high true spleen-rates are associated with serious infection even among the youngest infants. (3) Insufficient quinine is allotted to these natives, numbering about 22,000 persons; the amount of quinine sulphate distributed annually is less than 50 lb. weight. (4) If this race is to be saved, the distribution of quinine must be much increased. (5) It can conveniently be distributed by the method of the "medicine market," or by individual headmen. (6) Muruts and Ranau Dusuns should now and for ever be granted exemption from poll-tax or any other form of direct taxation.

SCOTLAND

(FROM OUR OWN CORRESPONDENT)

ANTERIOR LOBE OF THE PITUITARY

AT a recent meeting of the Edinburgh Obstetrical Society Dr. J. H. Biggart, pathologist to the Scottish Asylums Board, described investigations he has made on the basophil cells of the anterior lobe of the pituitary. After castration in the human, he said, the anterior lobe shows an increase in basophil cells, and coarse vacuoles appear in these cells. Since there are at present no histological criteria of the activity of secretion in the pituitary gland, Dr. Biggart has studied the occurrence of this vacuolisation. As many as 1000 human pituitary glands have been examined from this point of view, and he has found that there is no correlation between the occurrence of this change and the presence of toxæmias, septic processes in the gland or brain, tuberculosis, encephalitis, or vascular lesions. When the change was considered in relation to the patient's age it was found that in women the vacuolisation was constantly present after the menopause. The changes in the men, however, did not show a similar age-incidence, and Dr. Biggart suggests that there is some relationship between vacuolisation in the male pituitary gland and the activity of the seminal epithelium. On counting the basophil cells in various cases, he notes that these cells are greater in number after the menopause, but the increase is much less than that seen after castration. No correlation could be found between basophil invasion of the posterior lobe and hypertensive conditions, and Cushing's observations on the occurrence of this change in eclampsia were not confirmed.

Dr. Biggart thinks it probable that the basophil cells manufacture and store part at least of the gonadotropic hormone, but conclusions about the functions of these cells are made difficult by the fact that they react to other conditions, such as Addison's disease and nephritis. His investigations do not confirm Woollard's contention that the basophil cells merely inhibit the activity of the eosinophils.

FULL-TIME MEDICAL SERVICE FOR THE POOR

The public health and public assistance committees in Glasgow have decided to advise the corporation to organise a full-time medical service for the poor. This work is at present undertaken by doctors on a part-time basis. The local division of the British Medical Association has advocated a system similar to that of the panel under the health insurance scheme, but the majority of the counsellors, who have made a special study of the situation, have preferred to recommend that the work be undertaken by a permanent medical staff. The estimated cost of the service is £20,000 a year.

RED CROSS SOCIETY

The latest annual report of the Scottish branch of the British Red Cross Society states that there are now over 4000 members enrolled in the detachments, and of these over 1000 have undertaken to serve in any part of the world to which they may be sent on the outbreak of war. Much attention has recently been paid to the training of members for first aid in chemical warfare, and 800 members have already undergone such training.

PARIS

(FROM OUR OWN CORRESPONDENT)

PROF. JEANSELME

THE death of Jeanselme removes a man prominent in French medicine. On the subjects of dermatology, venereal disease, and leprosy he was encyclopædic, and his authority in these spheres was unchallenged. At the time of his death he was engaged on a monumental study of syphilis, four volumes of which have already appeared, while four others are either in the press or still incomplete. In the campaign against venereal disease he was an advocate of the regulation of prostitution, and over this subject he broke many a lance with the abolitionists. His attitude was, however, always judicial, and his strong historical sense gave him a perspective which saved him from many hasty conclusions. In collaboration with Burnier he did much to develop the venereal disease dispensary which he organised as an information service. Thanks to the statistics obtained from this source, he was able to show that, in the Paris area, the decline in syphilis between 1920 and 1924 was followed by a rise traceable to the too early cessation of treatment, to the development of clandestine prostitution, and to lack of sex education among women. He was, in fact, a great believer in sex education as a weapon against v nereal disease.
His interest in the history of med was not con-
fined to syphilis, and he was pr of the French
Société d'Histoire de la Médec 20 and 1921.
He was also one of the found ociété Inter-
nationale d'Histoire de la he presided
over its congress in P Among his
historical studies was of disease
on the military cam *Indeed, the*
history of medicine eanselme's greatest pre-
occupation during the latter part of his life.

of antidiphtheritic serum ; her illness was mild and uncomplicated.

I am indebted to Dr. A. E. Hodgson, medical superintendent of the hospital, for guidance in the clinical management of the incident and for permission to publish this account of the outbreak.

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDED MAY 11TH, 1935

Notifications.—The following cases of infectious disease were notified during the week: Small-pox, 0 ; scarlet fever, 2052 ; diphtheria, 1015 ; enteric fever, 21 ; acute pneumonia (primary or influenzal), 944 ; puerperal fever, 43 ; puerperal pyrexia, 116 ; cerebro-spinal fever, 17 ; acute poliomyelitis, 5 ; encephalitis lethargica, 4 ; dysentery, 12 ; ophthalmia neonatorum, 72. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the London County Council on May 17th was 3271, which included : scarlet fever, 996 ; diphtheria, 1319 ; measles, 32 ; whooping-cough, 391 ; puerperal fever, 25 mothers (plus 5 babies) ; encephalitis lethargica, 269 ; poliomyelitis, 3. At St. Margaret's Hospital there were 21 babies (plus 12 mothers) with ophthalmia neonatorum.

Deaths.—In 121 great towns, including London, there was no death from small-pox, 2 (0) from enteric fever, 28 (1) from measles, 7 (0) from scarlet fever, 24 (4) from whooping-cough, 29 (8) from diphtheria, 46 (15) from diarrhœa and enteritis under two years, and 87 (7) from influenza. The figures in parentheses are *those for London itself.*

No great town reported more than 6 deaths from influenza, this was the number at Manchester ; 4 deaths were reported from Leeds, Newcastle-on-Tyne, Sheffield, and Birmingham. Eight fatal cases of measles occurred at Wigan, 4 at Sunderland. Preston and Exeter reported the two fatal cases of enteric fever.

The number of stillbirths notified during the week was 293 (corresponding to a rate of 44 per 1000 total births), including 45 in London.

MEDICINE AND THE LAW

Unsuccessful Action for Negligence against Surgeon

IN Cain *v.* Davis Mr. Justice Branson rejected a claim for damages based on allegations that a surgeon had negligently left a swab or pieces of gauze in the body of a child after an operation. Mr. K. J. Acton Davis had operated in March, 1932, on the child at the Princess Elizabeth of York Hospital for Children, where he is senior surgeon. Subsequent operations were performed by other surgeons when an abscess formed. In November 1933, pieces of gauze were expelled through the operation wound. The evidence of X ray photographs, taken in January, 1933, showed no trace of a foreign body in the operation wound. Mr. W. E. Miles, consulting surgeon to the Cancer Hospital and the Royal Hospital, Richmond, stated that the fact that the wound remained healed for six or seven months was proof positive that no foreign body was present. The defence was that swabs and not gauze were used in the course of the operation conducted by Mr. Acton Davis, and that nothing was left in the child's body. On the other hand, the child's mother and the nurse who attended the child after the subsequent operation both stated that no gauze was then used for plugging the wound. The judge found that the gauze entered the child's body at a date subsequent to the first operation. "I am satisfied," he said, "that, if the onus had been upon Mr. Acton Davis to prove that the pieces of gauze were not left behind, I should have held him to have discharged that onus by affirmative proof that they were not."

Two points about the case may be worth noting. In the first place the trial took place before a judge without a jury, so that the hearing was probably shortened and there was the less temptation to introduce considerations of sentiment such as are sometimes addressed to juries. Secondly, counsel for the plaintiff seemed anxious not to impute direct negligence to the surgeon. In his final speech he observed that Mr. Acton Davis had one advantage in the witness-box because everybody would know at once that, if he had done anything negligent, he was absolutely unconscious of it at the time ; the negligence alleged was the negligence of not observing something or of completely forgetting something he had done. "If," said counsel, "the court should find against Mr. Acton Davis, one hopes he will look upon himself as unfortunate rather than as one to whom the smallest stigma of incompetence or negligence is attached." This was a curiously apologetic way of pressing home the final stage of an assault upon a surgeon's professional conduct. Fortunately the assault was decisively repulsed.

Drug Addiction as an Occasion for Divorce

In the medico-legal section of a German medical weekly (Münch. med. Woch., May 9th, p. 771) is set out a decision of the Düsseldorf appeal court. A man who had years before been given morphine for relief of pain began to give himself injections and finally became a morphinist. He pawned his household goods, got into debt, and was in trouble for infringement of the law against traffic in dangerous drugs. When he could obtain no money for morphine he threatened his wife and caused her grievous bodily injuries. Article 1568 of the Bürgerliches Gesetzbuch gives as a sufficient reason for divorce when default of the duties implied in the marriage contract occasions so grave an interference with marital relations that prolongation of the marriage can no longer be reasonably expected. In this case the morphine habit was deemed incurable, although the man was not actually a psychopath. He had several times been in an institution but had always relapsed on coming out ; if his morphine habit was incurable he was himself to blame for it, as he left before completion of his cure. The incurable addiction of one spouse having led to complete break-up of the marriage a divorce must be granted to the other.

The German code, it will be observed, makes no specific allusion to drug addiction as a ground of divorce. The laws of other countries are similarly silent. Chronic drunkenness is a ground of divorce in many of the States of America, in Greece, and elsewhere, and, when other elements are present, in Australia and New Zealand. In England we obstinately refuse to enlarge the grounds of dissolution of marriage, in spite of the efforts of reformers like Lord Buckmaster. Even incurable insanity, recognised for this purpose in Sweden, Switzerland, Germany, and elsewhere, is not ground for divorce in England. The attitude of our Parliament, which has shown itself hitherto remarkably unwilling to weaken the marriage tie, may be contrasted with the elastic spirit of French law. One of the grounds of divorce in France is moral cruelty (*injures graves*). The standard examples in the French courts include excessive and unjustifiable jealousy on the husband's part, refusal to keep a promise to proceed to the religious ceremony after the civil marriage, publication of seriously defamatory statements about the petitioner, and insistence on the use of contraceptives.

OBITUARY

THOMAS WALTER HARROPP GARSTANG,
M.A. Oxon., M.R.C.S. Eng., D.P.H. Manch.

THE recent death of Dr. T. W. H. Garstang has removed from the profession one who played a prominent part in much medico-political work. After graduating in arts at Oxford he entered St. Bartholomew's Hospital as Jeaffreson exhibitioner, qualified as M.R.C.S. Eng., L.S.A. Lond. in 1878, was a prizeman, and for a time resident obstetric assistant at the hospital. His early work showed practical interest in obstetrics, but later he turned towards public health, took the diploma of D.P.H Vict., and held appointments as medical officer of health under a series of urban and rural district councils, and was for a time medical superintendent of a temporary fever hospital in Knutsford. But Garstang was chiefly known to the medical world for his long and important association with the British Medical Association. He was a member of the council for two periods, and of the Representative Body off and on for over 20 years, while he acted as chairman of this body from 1918 to 1921. He was elected vice-president of the B.M.A. in 1926, and was at different times a member and more than occasionally chairman of important organisations and medico-political committees of the association. At the age of 70 Garstang resigned his appointments and retired from all active participation in professional affairs.

MARY ETHEL JEREMY, M.B., B.Ch. R.U.I., O.B.E.

Dr. Mary Jeremy, whose death has been announced, was the daughter of a Dublin clergyman. She received her medical education at the London School of Medicine for Women, and graduated M.B., B.Ch. from the Royal University of Ireland in 1906. After holding certain resident appointments in London she went to India on missionary service, and became staff officer at the Memorial Hospital, Ludhiana, Northern India. She returned to England during the war and held an appointment at the Southampton War Hospital, where her excellent services were recognised at the close of hostilities by appointment as O.B.E. Later she played a prominent part in various social organisations. The medical profession has lost in her a valuable member.

THE LATE FIELDING GARRISON

THE annotation on Fielding Hudson Garrison, the distinguished bibliographer who recently died, which appeared in THE LANCET last week, has brought to us a letter written by him and inspired by the review in THE LANCET of his "Introduction to the History of Medicine." The letter was addressed to the late Dr. H. P. Cholmeley, at that time assistant editor of THE LANCET, whom he had learned to be the author of our review. He writes: "A copy of THE LANCET, containing your very generous and discriminating editorial on my book on medical history, is received, and I beg to express my cordial thanks for this courtesy. In particular, I feel more than grateful that you have emphasised my primary intention of making a guide-book or handbook of the subject rather than a profound or exhaustive treatise. In spite of my explicit avowal in the preface, some reviewers in this country have taxed me with not going deeply enough into the subject. My own studies, which have been mainly bibliographical, have been sufficient to convince me that the entire field is, as you say, almost too vast to be handled by any single man, and I did not make my disclaimer in a spirit of mock-modesty." There is no doubt that Garrison's book, and the facilities offered by consultation of the Index Medicus under his editorship, led to the publication of many of the interesting biographies of the leaders of American medicine which have appeared in the last 20 years, a number of which have been reviewed in our columns.

PARLIAMENTARY INTELLIGENCE

NOTES ON CURRENT TOPICS

The Question of Decentralising Public Health in India

IN a debate on the Government of India Bill in the House of Commons on May 13th Mr. H. WILLIAMS moved to omit Public Health and Sanitation from the list of subjects to be dealt with by the provincial legislatures. Public health, he said, was not something which had any knowledge of provincial boundaries; if an outburst of bubonic plague were handled by provincial governments working separately great danger to the public health would ensue.—The Duchess of ATHOLL in supporting the amendment recalled the admirable measures proposed by the central government for preventing the extension of an epidemic from one province to another. She cited the high maternal death-rate and the scantiness of child welfare work as arguments in favour of the need of central authority.—Mr. BUTLER, Under-Secretary for India, in opposing the amendment, said that the concurrent list met the difficulty of disease which might cross provincial boundaries. Public health had been a provincial subject ever since the reforms were introduced twelve years ago, and the Government followed the Statutory Commission in its unwillingness to take away this subject from the provinces.

The differences between the provinces as regarded the incidence of disease, followed, unfortunately, provincial idiosyncrasies. The registration of infectious diseases might have to be enforced in a different way in one province from that in which it was enforced in another. It would be very difficult, in the case of any particular disease which ravaged one particular province, for the federal legislature to pass a law which necessarily suited that province. The manner of dealing with malaria in Bengal might be radically different from the manner of dealing with it, say, in the Punjab, and he was advised by the Government's experts that it would not be conducive to the extinction of malaria if they were to insist on regulation by a Central Act of the provincial treatment of malaria in different parts of India. In order to eradicate disease and have an efficient public health and sanitary service it was essential to encourage local effort and provincial autonomy in dealing with these matters. Moreover, these public health matters depended essentially on provincial finance.

It would be possible, under an item of the Federal List, for institutions for research to be governed from the centre. That matter could be governed by federal legislation. The Government considered that the most fruitful course to pursue in dealing with these problems was that of the coördination of policy between the centre and the units. Recently a department of health ha[illegible] been established in Australia entirely by the process [illegible] coördination and coöperation between the units an[illegible]ot by any artificial control from the centre. In Indi[illegible]ey hoped the future would follow much the same lines. Under Clause 133 of the Bill the Government had included the opportunity for the provinces to set up an inter-provincial council, and he hoped that further coördination in health policy might result. He had discussed this matter with Major-General Graham and others connected with public health in India.

Mr. ORMSBY GORE, First Commissioner of Works, said he devoutly hoped the Government of India would not try to impose antimalarial measures on the provinces, for it was of the utmost importance *not* to have uniformity in preventive measures dealing with malaria. In a rice-producing country they could not have too much water as a preventive; in a wheat-producing country, on the other hand, a maximum of drainage was required. Probably the greatest success in fighting malaria had been achieved by concentration in a limited area. Where the central government had adopted a sort of mass attack it had almost invariably failed. He deprecated blaming the failure of Indian Ministers to grow quinine in competition with Java, which had a monopoly because cinchona could be grown more cheaply there than in other places.

The amendment was negatived by 216 votes to 31.

Restriction of Ribbon Development

In the House of Lords on May 16th the Earl of PLYMOUTH, Under-Secretary of State for the Colonies, moved the second reading of the Restriction of Ribbon Development Bill. The main arguments in support of a measure of control of this kind were, he said, of a dual nature. There were the traffic and safety arguments and there was the æsthetic argument. Both types of argument were of great importance and together formed an overwhelming case for action. The figures showing the number of fatal and other accidents which had occurred on our roads during the last year or two were undoubtedly very alarming. In the last year over 7000 people were killed on the roads, and out of that number some three-quarters, he thought, had been killed in what were known as built-up areas. It was far too early to express any opinion at present as to whether the new 30 miles an hour speed limit recently imposed was likely to constitute a remedy for this state of affairs. He did not think that anybody suggested that in itself this or any other measure that the Government could take would alone solve the problem of casualties on our roads; but whether that was so or not the fact remained that ribbon development did create conditions which were dangerous and should therefore be checked. It was clearly undesirable, unpleasant, and obnoxious that the appearance of our highways and the beauty of the country which surrounded them should be impaired and very often entirely ruined by the disorganised, unsightly, and highly dangerous method of ribbon development. The communal aspect of the problem was another important point. It was obviously desirable to plan buildings in such a way as to establish villages or townships rather than to allow haphazard methods of providing the habitations of the community to grow up with all their resultant evils. While he could not regard as feasible any general legislation which would guarantee the public against losing at one place or another an uninterrupted view of the countryside, the Government certainly believed that it was within the sphere of practical politics to provide for the proper and orderly development of lands adjacent to the highway.

The Bill brought the control, so far as it concerned the acquisition of roads, into operation immediately on the passing of the Act. This was a point which they had been urged from many quarters to secure. This meant that the requirement of consent of the appropriate highway authority for [illegible] and for the formation of new means of ac[illegible] e line of 40,000 miles of roads, which wer[illegible] por- tant roads from the traffic point o[illegible] d be applied automatically and at once. The Government thought that it would be going too far to apply this procedure automatically to the remaining 130,000 miles of roads in the country, but they had provided in the Bill that the highway authority might in the case of any unclassified road where such control would be desirable by resolution and with the concurrence of the Minister of Transport apply the provisions of this clause to that road also. Steps would doubtless be taken while the Bill was still before Parliament to draw the attention of the highway authorities to this power so that they might be in a position to act as soon as the Bill was passed into law.

AN AMENITY BUILDING LINE

This general power of control for 220 feet on either side from the middle of the road might be conveniently described as the provision of an amenity building line. But their purpose would be incompletely achieved if this provision resulted merely in setting back to a distance of 200 feet from the highway the ribbon development. What they aimed at really was to aid the highway authority to encourage ordered development, and in particular ordered group development. At the same time it was essential to provide from the more limited traffic standpoint that on the more important routes all possible steps should be taken to safeguard land which might be required to be thrust into the highway at a later date in order to provide sufficient width of road for increased traffic requirements, including where necessary dual carriage ways, footpaths, and cycle tracks, and in appropriate cases subsidiary service roads. They were accordingly taking powers in the Bill to enable the highway authority with the Minister's approval to adopt for any highway one of a number of scheduled standard widths of the road between fences. Within the standard width the highway authority was to be empowered to prohibit buildings and works of all kinds other than defined improvements of existing buildings, and powers in default were given to the Minister of Transport in cases where the authority was held to have failed to take the necessary steps for safeguarding the line of the road required for the safe and adequate passage of traffic in the future. These powers could only be exercised by the Minister after a public inquiry. The maximum standard width set out in the Bill was 80 feet from the middle of the road, which meant an all-over width of 160 feet.

CONTRIBUTION FROM THE ROAD FUND

In so far as restriction related to the standard width line—that was the land which would be ultimately required for the purposes of the highway—the Bill proposed expressly to authorise contributions in respect of compensation to be made from the Road Fund. The Bill also gave highway authorities powers for the compulsory acquisition of land adjacent to highways for the purpose of the creation of parkways and the like. The general powers of the Bill were not only conferred on county councils but also on the councils of county boroughs. They provided also for the roads for which the councils of non-county boroughs and urban districts were responsible. The Minister of Transport was anxious to include in the Bill provision for dealing with certain urgent problems of road congestion in towns. The powers of local authorities to provide parking places were enlarged so as to enable them to provide parking accommodation for vehicles in buildings or underground.

The Government had considered very carefully whether it would in any way be practicable to make the operation of the Bill retrospective in its effect. as it has been suggested to them that recent public utterances as to the urgent need for this legislation had only spurred the ribbon developer to greater activity before a new control was imposed upon him. [illegible] that as it might—and he might say parenthetically [illegible] Government has no definite evidence that [illegible] been the case—they did not feel that they [illegible] perly immobilise all development, good as [illegible], between now and the date of the passage

OPPOSITION SUPPORT

Lord MARLEY said he supposed that everyone who had driven on the by-pass roads must have seen the dangers to traffic of the building up of these small houses close alongside roads which were intended not for small houses but for rapid traffic. They saw that every day the damage was extending and that the spread out along the main thoroughfares of ribbon development now taking place on all the most important roads aroused serious concern and called for immediate action. The remedy for these difficulties was in the development of the group system of building houses. The large development of the group system—the development of satellite towns—was again a system for preserving the great through roads for rapid traffic and for making easier and cheaper the supply of services to the new communities. The Opposition had decided that—in spite of the fact that there were naturally from their point of view imperfections in the Bill—in order in every possible way to expedite its passage through the House they would move no amendments. They appealed to the Government to be prepared to consider this only as a preliminary Bill, to be followed by an amending Bill to meet any deficiencies or defects in the working of the present measure.

The Bill was read a second time and committed to a Committee of the whole House.

Foot-and-Mouth Disease Research

In the House of Lords on May 21st Lord STRACHIE raised the question of the recent serious outbreak of foot-and-mouth disease in Dorset, and mentioned that it was desirable that the Minister of Agriculture should have power to prohibit the introduction of hay and straw or other imports into Great Britain from countries where foot-and-mouth disease was known to exist. He said that recent outbreaks had cost the country £70,000 for the slaughter of 5418 animals.—Earl DE LA WARR, Parliamentary Secretary to the Ministry of Agriculture, in his reply, said that the fact probably was that with regard to all these outbreaks there was a great variety of causes, but never had it been possible to trace infection to any one source. A foot-and-mouth disease research committee under the chairmanship of Dr. Arkwright had been examining the question. They have been particularly studying immunity and it was hoped that they would shortly issue an interim report on the source of the disease. If anything transpired from the investigation the Government would not be slow to take up any suggestions and put them into effect.—The motion was withdrawn.

HOUSE OF COMMONS

WEDNESDAY, MAY 15TH

Hospital Accommodation in Palestine

Captain STRICKLAND asked the Secretary of State for the Colonies whether he was aware that inhabitants of Tel-Aviv, Palestine, in need of hospital treatment, had in many cases to be transferred to hospitals in other parts of the country because of lack of available beds in the municipal hospital; and whether he was yet in a position to state if the government had decided to accede to the request of the municipal authority of Tel-Aviv to be permitted to provide the necessary additional and improved accommodation.—Sir PHILIP CUNLIFFE-LISTER replied: I am not in a position to confirm the statement contained in the first part of the question. As promised in my answer to a question on April 3rd, I have communicated with the High Commissioner for Palestine, but I have not yet received information as to the intentions of Government regarding the proposals for financing the enlargement and improvement of the hospital. I should add that during last year this hospital, to the cost of which the Government contributes, was enlarged from 125 to 184 beds.

National Health Insurance: New Bill Promised

Miss WARD asked the Minister of Health whether he was yet in a position to make a statement regarding the Government's proposals for dealing with persons who had fallen out of national health insurance.—Mr. SHAKESPEARE, Parliamentary Secretary to the Ministry of Health, replied: My right hon. friend hopes to introduce legislation on this subject very shortly.

Miss WARD: Is the hon. Member in a position to say that the medical side will be considered, as this matter is causing great anxiety to a number of people?

Mr. SHAKESPEARE: I do not think my hon. friend will have long to wait, but I cannot anticipate the terms of the Bill.

Mr. G. GRIFFITHS: Will the maternity side be considered?

Mr. RHYS DAVIES: May we take it that the Bill will be passed through all its stages before the end of July?

Mr. SHAKESPEARE: Obviously I cannot guarantee that, but we should like it to do so.

Diphtheria in Leeds

Mr. GROVES asked the Minister of Health whether there had been any deaths from diphtheria in Leeds children who had at any time been inoculated against diphtheria; and (2) if he would state the number of children under 15 years of age in Leeds who were inoculated against diphtheria in each of the years 1928, 1929, 1930, 1931, 1932, 1933, and 1934; the number of those inoculated in these years who gave the final Schick-negative test; and the number of those who, having been inoculated and given final Schick-negative tests, contracted diphtheria in each of these years.—Sir HILTON YOUNG replied: The following is the information furnished by the local authority on this subject:—

Year.	Children under 15 years inoculated.	Those inoculated who gave final Schick-negative test.	Those inoculated with final Schick-negative tests who contracted diphtheria.	Deaths from diphtheria in Leeds children who had been inoculated against diphtheria.
1928	92	65	Nil	Nil
1929	101	73	Nil	Nil
1930	174	152	Nil	Nil
1931	602	202	Nil	Nil
1932	1874	1379	6	Nil
1933	1372	1030	1	Nil
1934	2773	2226	4	Nil
Totals	6988	5127	11	Nil

THURSDAY, MAY 16TH

Industrial Disease as an "Accident"

Mr. TINKER asked the Home Secretary if he was aware that persons who had had industrial disease were being refused employment when they signed that they had had it; and would he consider amending Section 9 (4) of the Workmen's Compensation Act so as to make it clear that the word injury included disease, so as to enable those who were unable to get employment through having had an accident or industrial disease should be treated the same.—Sir JOHN GILMOUR replied: I am aware that colliery owners often refuse employment to men who have had nystagmus, but as explained in previous replies, the issue is by no means a simple one, and in my opinion a full inquiry into this and other questions connected with the payment of compensation for this disease would be necessary before any amendment of the law could be usefully considered.

Mr. T. SMITH: Is it the intention of the right hon. gentleman to institute an inquiry, in view of what has taken place in various parts of the country?

Sir J. GILMOUR: All I can say is that the matter is being very carefully considered at the present time.

Health Insurance (Dental Benefit)

Captain CUNNINGHAM-REID asked the Minister of Health whether, as persons insured under the national health insurance scheme were ineligible for dental treatment until they had been paying contributions for over four years, and in view of the importance of early treatment in dental cases, especially among young persons, he would consider the alteration of these regulations.—Sir Hilton Young replied: Under the National Health Insurance Acts dental benefit is not included in the statutory benefits to which all insured persons are entitled, but is an additional benefit which may be provided by an approved society having a disposable surplus as a result of a quinquennial valuation. An insured person becomes entitled to dental benefit at the beginning of the third year following that in which he joins a society providing the benefit. In fixing this waiting period regard has been had to the considerations referred to by my hon. friend, but I am afraid that any further shortening of the period would be open to serious objection not only on administrative and financial grounds but also from the point of view of equitable distribution of the surplus amongst the members of the societies.

Milk Marketing Board

Major Carver asked the Minister of Agriculture what additional percentage of milk was being handled by the Milk Marketing Board compared with the amount handled when it started its operations.—Mr. Elliot replied: The average daily quantity of milk sold under wholesale contracts during the six months ended March 31st, 1935, showed an increase of 17¾ per cent. on the average daily quantity in the corresponding period of the previous year. The quantity sold under wholesale contracts in April, 1935, was 23 per cent. more than that sold in April, 1934. The information is not available which would permit a comparison between the volume of sales by producer-retailers in the six months ended March 31st, 1934 and 1935 respectively, and therefore I am unable to give a figure representing the percentage increase in the total supplies of milk coming under the Milk Marketing Scheme then and now.

Disease Carriers

Captain Erskine-Bolst asked the Minister of Health how many human disease-carriers were known to his department; what diseases were thus carried; and what was the general policy of his department with respect to the surveillance of such cases.—Sir Hilton Young replied: The number of human disease-carriers about whom information is available in my department is necessarily small, but I am advised that most infectious diseases are capable of being carried in this way, and that all persons may be carriers of some disease at one time or another, though not of course necessarily responsible for the spread of the disease. The policy of my department is that known carriers of disease should not engage in any occupation which would render them a special source of danger to the public.

Mr. Groves asked the Minister of Health what precautions were taken by medical officers of health to make sure that they themselves were free from infection by the hæmolytic streptococcus and could themselves carry the contagion.—Sir Hilton Young replied: I am advised that the best and perhaps the only precautions that can be taken are those measures for preserving surgical cleanliness that are familiar to medical practitioners.

MONDAY, MAY 20TH

The Training of Hospital Nurses

Mr. Remer asked the Minister of Labour whether he was aware that there was a shortage of trained hospital nurses; and if he would consider allocating some portion of public funds in the distressed areas to educate and train a limited number of suitable girls as hospital nurses either in the great hospitals locally or in hospitals in the south of England.—Mr. R. S. Hudson, Parliamentary Secretary to the Ministry of Labour, replied: I am aware that there is some shortage of trained hospital nurses in certain places. I understand, however, that the shortage is not due to any lack of training facilities as in the majority of hospitals the training is provided free.

Prevention of River Pollution

Captain Cunningham-Reid asked the Minister of Health whether the Government had yet begun to prepare a River Pollution Prevention Bill; whether it was hoped that such a Bill would prove to be non-controversial; and when it was proposed to be introduced.—Mr. Shakespeare replied: My right hon. friend presumes my hon. friend's reference is to a Bill to provide for the reception of trade effluents into sewers. The state of Parliamentary business precludes any measure this session, but my right hon. friend has in mind the case for such a measure, and, while he cannot say that it would be without controversy, he hopes that the negotiations which have taken place will result in substantial agreement.

TUESDAY, MAY 21ST

Inquiries into Maternal Deaths

Colonel Clifton Brown asked the Minister of Health if he had considered the suggestion made at the annual meeting of the Carlisle and District Nursing Association, to which his attention had been drawn, that inquests should be held on every maternal death in order to draw public attention to the many avoidable causes of these fatalities; and what action he proposed to take in the matter.—Mr. Shakespeare replied: This suggestion was considered by the Departmental Committee on Maternal Mortality and Morbidity, who did not advocate its adoption (Final Report, pp. 26–27). The committee advised that local authorities should be urged to continue the arrangements by which medical officers of health make inquiries into maternal deaths and furnish confidential reports to the chief medical officer of my department. My right hon. friend has taken action accordingly.

Methylated Spirit Drinking

Mr. Leckie asked the Home Secretary whether he had considered a communication from Dr. Percy Turner, chief medical officer of the Salvation Army, on methylated spirit drinking; and whether, in view of the facts therein described, he proposed to carry out the suggestions made for dealing with the problem.—Mr. Duff Cooper, Financial Secretary to the Treasury, replied: I have seen a copy of the *British Journal of Inebriety* containing an article by Dr. Turner, in which he suggests that changes in the denaturing of methylated spirits might be considered. The matter is one which engages constant attention, but on the evidence at present available I am not satisfied that any alteration is expedient.

L.C.C. HOSPITALS

The one-storey building at Hammersmith Hospital to provide suites of offices for three professors, four laboratories, and a students' common room is to be proceeded with at once, the Minister of Health having consented to the alienation of the land. The cost will be borne by the medical school.

An out-patient department has been opened at Five Elms on the Becontree estate as an adjunct to the King George Hospital at Ilford, from which doctors, nurses, and masseurs will be supplied. The Becontree health centre and out-patient department, as it is called, will provide for the treatment of accidents and other casualties, and certain minor ailments.

Some forthcoming changes of staff are announced. Dr. J. H. Whitaker, medical superintendent of the Grove Hospital, and one of the Council's small-pox diagnosis consultants, will shortly retire under the age limit. He entered the service of the M.A.B. 38 years ago. Dr. J. S. Anderson will take his place. Dr. Maurice Mitman is to be promoted to be a divisional officer in the public health department; he is at present deputy medical superintendent and radiologist at the North Eastern Hospital. Dr. A. D. Morris, at present senior assistant medical officer at the Hammersmith Hospital, will become medical superintendent of St. Leonard's Hospital and acting master of the institution.

MEDICAL NEWS

University of Cambridge

On May 17th the following degrees were conferred :—

M.D.—Henry Barcroft and G. H. Day.

M.B., B.Chir.—F. H. Coleman.

English Conjoint Board

At the recent final examination of the Board the following candidates were approved in the subjects indicated, but are not yet eligible for the diplomas of the Colleges :—

Pathology.—R. B. Abdel-Messih, St. George's ; H. L. Ackerman, Lond. ; I. Affleck, Charing Cross ; S. G. Alavoine, Lond. ; M. M. Ali, St. Bart.'s ; G. A. Armstrong, Westminster ; J. H. Armstrong, St. Bart.'s ; S. Balasingan, King's Coll. ; S. Ball, Liverp. ; H. D. G. Barnes, Lond. ; J. E. M. Barnes, St. Mary's ; H. H. F. Barns, Univ. Coll. ; Mary J. Bartlett, Roy. Free ; P. N. Baruah, Manch. ; L. Bass, Middlesex ; A. B. Baxter, Guy's ; S. L. Bhatia, Roy. Free ; K. O. Black, St. Bart.'s ; G. N. Blackburn, Leeds ; B. E. Blair, St. Thos. ; F. A. Bleaden, Guy's ; Katherine M. Blenkin, Roy. Free ; K. E. Bond, Camb. and St. Thos. ; J. C. B. Bone, Middlesex ; T. F. Bostock, St. Bart.'s : C. M. Bowker, St. George's ; J. D. Bradley-Watson, St. Bart.'s ; W. G. Brander, Camb. and St. Thos. ; G. C. Brentnall, St. Bart.'s ; A. J. Broomhall, Lond. ; A. G. T. Brown, Guy's ; J. C. Brundret, Manch. ; D. H. D. Burbridge, Middlesex : P. J. Burke, Manch. ; W. A. Burnett, Middlesex ; J. C. Busby, Camb. and St. Mary's ; Josephine H. Campbell, King's Coll. ; N. R. Chan-Pong, Birm. ; L. S. S. Chiew, Singapore ; Priscilla B. Clark, Univ. Coll. : E. P. Clarke, St. Bart.'s ; R. R. Clipstein, St. Mary's ; D. H. Coe, King's Col. ; C. D. Coode, Oxon and Lond. ; G. F. Crickmay, St. Thos. ; M. Curwen, and S. Curwen, Middlesex ; V. R. Damle, Bombay and Lond. ; C. S. Darke, Guy's ; A. B. Dempsey, Lond. ; P. R. Dias, King's Coll. ; E. N. Dowell, St. Mary's ; T. P. Eddy, Oxon and Middlesex ; Dora J. B. Falconer, Roy. Free ; M. Royal College of Physicians of London

A Leverhulme research scholarship will shortly be awarded by the College for the investigation of "some problem of disease in any branch of medicine." Applications should reach the assistant registrar at the College, Pall Mall East, S.W. 1, before June 10th. Further particulars will be found in our advertisement columns.

Pharmaceutical Society

At a meeting of this society held on May 15th it was announced that as the leases of its present premises are coming to an end it has been decided to erect a new building. A freehold site in Brunswick-square was acquired by the society in 1929, and the estimated cost is £195,000.

Royal College of Surgeons of Edinburgh

At a meeting of the College, held May 15th, with Dr. A. H. H. Sinclair, the president, in the chair, the following candidates having passed the requisite examinations were admitted to the fellowship :—

Norman Stannus Gunning, M.B. Adelaide; John Alexander Baty, M.B. Edin.; Alan John Stuart Lawson Boyd, M.R.C.S. Eng.; William Huntly Chambers, M.D., Ontario; Robert Cochran, M.B. Glasg.; David Kenneth Crawford, M.B. Edin.; Howard Roderick Duval, M.D. Ontario; Henley Henderson Harrison, M.B. Sydney; Murray Hamilton Heycock, M.B., N.Z.; Ewen Alistair Jack, M.B. Edin.; Alexander Lewen Mackenzie, M.D. Toronto; David James MacRae, M.B. Edin.; Gerard Brendan Malone-Lee, M.R.C.S. Eng.; Thomas Love Masterson, M.D. St. Andrew's; Arthur Ralph Rex Mears, M.R.C.S. Eng.; Michael Robert Sheridan, M.B. Liverp.; Ian Scott Smillie, M.B. Edin.; and Ernest Thompson, M.R.C.S. Eng.

The following candidates received the higher dental diploma :—

R. D. Johnston, S. C. Scarsdale Brown, C. A. Palk, H. S. R. Sarson, and A. O. Sutcliffe.

Imperial Cancer Research Fund

Dr. William Ewart Gye, M.D. Edin., will succeed Dr. J. A. Murray, F.R.S., as director of the fund on the latter's retirement at the end of this year.

Dr. W. E. Gye was born in 1884 and educated at the Risly Latin School and the University of Edinburgh, where he qualified M.B. in 1912, taking the M.D. in 1913. As a student he won many prizes and scholarships, and immediately after qualifying joined the staff of the pathology department of the University of Edinburgh under Prof. J. Lorrain Smith. In 1913 Dr. Gye came to London to work in the laboratories of the Imperial Cancer Research Fund. In 1914 he joined the R.A.M.C. and served as a captain in France and Italy in charge of field laboratories and at the War Office. On demobilisation he returned to his post at the Imperial Cancer Research Fund for a few months, and in 1919 joined the staf [illegible] Council at the National Institute for M [illegible] stead. His scientific publications [illegible] mostly concerned with anaerobic infections and the ætiology of silicosis, and in cancer research with filtrable tumours.

The Silver Jubilee Exhibition

The exhibition, which will be open to the public on June 1st, will consist of illustrations of the work of local government for the past 25 years, and will probably include demonstrations by various classes of schoolchildren. The public health department will have exhibits of equipment now and 25 years ago, and discourses on the great progress illustrated by the exhibition will be given.

The Ambulance Service on Jubilee Day

The number of casualties dealt with by the accidents section of the London Ambulance Service on May 6th was 244 in response to 230 calls, the highest recorded since the "great slide" of Dec. 21st, 1927, when London streets froze after rain and over 2000 casualties occurred within an hour or two. The average time in reaching cases from the time of call was 6·2 minutes, and this achievement was rendered possible by the new organisation which enables the number of available ambulances to be increased from 18 to 32 on emergency. The only serious case of delay was due to the congestion in Trafalgar-square.

Dr. Barnardo's Homes

At the annual general business meeting of Dr. Barnado's Homes National Incorporated Association held on May 15th, it was stated that 116,649 destitute boys and girls had entered the homes to Dec. 31st last. A total of 16,925 children and young people were dealt with during the year, and 1607 boys and girls and babies were admitted to the homes—1466 permanently and 147 temporarily. The number in residence at the end of the year was 8345. These homes, it is claimed, have no red tape and no waiting-list: the need of the child is the only consideration. The address of the Association is, 18, Stepney Causeway, London, E. 1.

Noise Abatement

The Prime Minister will open, on May 31st, at the Science Museum, South Kensington, a Noise Abatement Exhibition which is being arranged through the Anti-Noise League. The exhibition will remain open throughout the month of June from 10 A.M. to 6 P.M. daily, and will conclude with a conference. This begins with a reception at 3 P.M. on June 26th, when Lord Horder, chairman of the League, with Lady Horder, will receive the guests. At 4.15 Mr. Hore-Belisha, Minister of Transport, will take the chair for a discussion on sound and noise to be opened by Mr. G. W. C. Kaye, D.Sc. Meetings will be held at 11.30 A.M. and 3 P.M. on the two subsequent days, when the chairmen will be Mr. Geoffrey Shakespeare, M.P., Mr. W. Ormsby-Gore, M.P., Lord Halifax and Mr. H. G. Wells, and the speakers Mr. H. G. Strauss, Mr. Hope Bagenal, Sir Henry Richards, and Lord Horder. During the exhibition a special display of noise-resisting materials will be shown at the Building Centre, 158, New Bond-street, W. The exhibition itself will present a comprehensive survey of the problem of noise, and will contain among other things a demonstration house incorporating the latest architectural and building designs and materials for sound-proofing and sound absorption. Further information may be had from the general secretary, Anti-Noise League, 66, Victoria-street, S.W. 1.

University of London

At a meeting of the senate held on May 15th Dr. A. St. G. Huggett was appointed to the chair of physiology at St. Mary's Hospital medical school, and Mr. J. Paterson Ross to the chair of surgery at St. Bartholomew's Hospital medical college, both from Oct. 1st.

Dr. Huggett, who was born in 1897, was educated at Wimbledon College, the City of London School, and St. Thomas's Hospital medical school, where he won the senior entrance science scholarship. Qualifying in 1918 he saw active service in North Russia with the Royal Army Medical Corps, and returned in the following year to the physiological department at St. Thomas's. Here his employment was at first part-time, and from 1922 to 1925 he held a Beit research fellowship. From 1925 to 1930 he was whole-time demonstrator, and by the latter year had graduated as M.B., Ph.D., and D.Sc. of London University. Appointment to a lectureship at Leeds followed, and since 1931 he has been university reader in pharmacology there, while remaining a member of the physiology staff. He has examined for the universities of Leeds and Manchester, and for the Royal College of Surgeons. Of his original work, observations on secretin and other subjects were published in collaboration with Prof. J. Mellanby. For some years he has been particularly concerned with problems of fœtal respiration.

Mr. Ross, who is 40 years old, qualified M.R.C.S. Eng. from St. Bartholomew's Hospital in 1917 after a distinguished career as a student. He joined the medical branch of the Royal Navy immediately, and after demobilisation returned to posts as demonstrator in physiology and pathology, and house surgeon at St. Bartholomew's. In 1920 he won the university medal in the M.B. Lond., took the F.R.C.S. Eng. in 1922 and the M.S. Lond. in 1928. In 1931 he was awarded the Jacksonian prize of the Royal College of Surgeons, and became a Hunterian professor of the College, and in the same year was appointed assistant surgeon to St. Bartholomew's Hospital, assistant director of the surgical unit, and reader in surgery in the University of London, as well as assistant surgeon to the West End Hospital for Nervous Diseases. He spent some months as associate in surgery at the neurological clinic of the Peter Bent Brigham Hospital in Boston, U.S.A., working with Prof. Harvey Cushing. His contributions to surgical literature have been chiefly concerned with neurological surgery, and in 1934 he published jointly with Prof. G. E. Gask a book entitled "Surgery of the Sympathetic Nervous System."

The Dunn exhibition in physiology for 1935 was awarded to Mr. R. D. Blachford (Guy's Hospital medical school), and the Dunn exhibition in anatomy was divided between Mr. A. G. Apley and Mr. P. H. Wood (University College).

Sir Ernest Graham-Little was reappointed, and Prof. M. Greenwood, F.R.S., appointed, to the senate for the period 1935–39.

On May 27th, 29th, and 31st at University College Dr. William McDougall, F.R.S., professor of psychology in Duke University, New Columbia, will lecture on psycho-analysis and social psychology. The lectures will be at 5.30 P.M., and Prof. Charles Spearman, F.R.S., will take the chair at the first.

University of Leeds

On July 1st the hon. degree of LL.D. will be conferred on Dr. Walter Elliot, Minister of Agriculture, and the hon. degree of D.Sc. on Dr. Harvey Cushing, professor of neurology in Yale University, U.S.A.

Glasgow Post-Graduate Medical Association

This association has arranged for a general medical and surgical course to be held from August 19th to Sept. 13th. The mornings will be occupied with general medicine and surgical diagnosis and minor surgery at the Victoria Infirmary and in the Western Infirmary, while the afternoons will be spent in studying special subjects. Clinical assistantships are also available in some of the institutions taking part in the work of the association. Further information may be had from the secretary of the association at the University, Glasgow.

Middlesex Hospital Medical School Centenary

The 100th anniversary of the foundation of the Middlesex Hospital medical school is to be celebrated on Wednesday, July 24th. In the afternoon the prizes and Medals won during the session 1934–35 will be presented to students by the Chancellor of the University of London, and on the same day there will be a "scientific evening." Both ceremonies will be held at the Middlesex Hospital. The students' centenary ball is to be held at the Dorchester Hotel on July 25th.

The "refresher course" and annual dinner will be held as usual during the last few days of September, and early in October respectively.

Calls to the Bar

On May 15th Dr. Fred Grundy (Inner Temple) and Dr. J. L. Moir (Middle Temple) were called to the Bar.

A Netherlands Information Bureau

To promote relations between the British Empire and the Netherlands and her colonies, a Netherlands and Netherlands Indies Information Bureau has been established in London. Its address is Shell-Mex House, Strand, W.C.2.

National Temperance Hospital

The tenth annual Macalister lecture will be delivered at this hospital (Hampstead-road, London, N.W.) on Thursday, June 20th, at 9 P.M., when Mr. Herbert Paterson will speak on medicine and magic. Medical practitioners are invited to attend and bring friends.

Memorial to Sir Donald MacAlister

On May 5th a stained-glass window in the war memorial chapel of the University of Glasgow was dedicated to the memory of Sir Donald MacAlister, principal of the university from 1907 to 1929 and chancellor from 1929 to 1934. The window has been placed in the chapel by the university court.

British Science Guild

At the annual general meeting of this guild to be held on June 12th, at 4.30 P.M., a lecture on Gas Defence will be given by Mr. J. Davidson Pratt, F.I.C., secretary of the Association of British Chemical Manufacturers. The meeting will take place in the lecture theatre of the Royal Society of Arts, John-street, Adelphi, London, W.C. The address of the guild is 6, John-street.

West London Medico-Chirurgical Society

Prof. Edward Mellanby, F.R.S., secretary of the Medical Research Council, will deliver the Cavendish lecture of this society on Thursday, June 13th, at 8.30 P.M., at the Kensington Town Hall. He will speak on proper feeding as the first essential for good physique and health. There will be a reception at 8 P.M., and the annual conversazione and medical and surgical exhibition will follow the lecture.

Manchester Medical Society

The annual general meeting of this society was held on May 1st. In taking the chair, the new president, Dr. Arnold Gregory, spoke of the services of Dr. E. Bosdin Leech, the retiring president, and referred to the successful conclusion of the society's centenary year under his presidency. After Dr. T. H. Oliver had given a short appreciation of the untiring work of Dr. Leech on behalf of the society, a presentation was made to Dr. and Mrs. Leech. Dr. Spence read a paper on England during the Black Death.

Industrial Accidents and Diseases

A British committee has been formed in connexion with the seventh International Congress on Industrial Accidents and Diseases, to be held in Brussels from July 22nd to 27th. The members include Sir Thomas Oliver, M.D. (chairman); Dr. D. A. Coles; Dr. Gilbert Burnet; Prof. E. L. Collis, M.D.; Colonel Donald J. Mackintosh, M.B.; Prof. S. L. Cummins, M.D.; Prof. John Glaister, M.D.; Colonel P. S. Lelean, F.R.C.S.; Dr. C. S. Thomson; Dr. S. A. Henry; Dr. T. E. A. Stowell; Dr. S. W. Fisher; Dr. Philip Ellman; Dr. Ronald E. Lane; Dr. Howard E. Collier; Lieut.-General Sir Harold Fawcus, M.B.; Dr. J. D. Byrd; Dr. W. Seaman Bainbridge; and Dr. Henry G. Kessler.

Post-graduate Courses in Berlin

International medical post-graduate courses are to be held in Berlin on the following subjects: internal medicine (Sept. 2nd–14th); intrathoracic surgery (Sept. 2nd–6th); tuberculosis (Sept. 9th–14th); infectious diseases (Sept. 16th–21st); throat, nose, and ear (Sept. 30th–Oct. 12th); and eugenics (Oct. 7th–12th). Monthly courses in all the special departments of medical science, including practical work, will also be held. Particulars may be had from the information bureau of the Kaiserin Friedrich-Haus, Robert Koch-Platz 7, Berlin, N.W. 7.

Medical Diary

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

Monday, May 27th.

Odontology. 8 P.M. (Royal College of Surgeons, Lincoln's Inn-fields, W.C.), Annual General Meeting. Sir Frank Colyer will show new specimens received in the Museum.

Tuesday.

Medicine. 5 P.M., Annual General Meeting. Dr. C. C. Ungley: Parenteral Liver Therapy in Pernicious Anæmia and Subacute Combined Degeneration. Dr. G. G. Kayne: Use of Sanocrysin in Pulmonary Tuberculosis. Dr. Burgess Barnett: Hæmostatic Uses of Snake Venom.

Wednesday.

Surgery. Provincial Meeting in Cardiff.

History of Medicine. 5 P.M., Dr. J. D. Comrie: Eighteenth Century English Medicine.

SOCIETY OF MEDICAL OFFICERS OF HEALTH, 1, Thornhaugh-street, W.C.

Fever Hospital Medical Services Group.

Friday, May 31st.—4.30 P.M., Dr. Murdoch McGregor, Dr. H. S. Banks, and Mr. T. B. Layton: Incidence and Management of Scarlet Fever Otitis.

BRITISH PSYCHOLOGICAL SOCIETY.

Medical Section.

Wednesday, May 29th.—8.30 P.M. (11, Chandos-street, W.), Mr. P. E. Vernon: The Rorschach Inkblot Test in the Light of Recent Research.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

Monday, May 27th, to Saturday, June 1st.—Maudsley Hospital, Denmark-hill, S.E. Afternoon course in psychological medicine.—St. John's Hospital, [illegible] W.C. Afternoon course in derma- [illegible] all.)—Chelsea Hospital for [illegible] S.W. Course in Gynæcology.—*City of London Hospital*, Victoria Park, E. *All-day* course in Chest diseases.—London Lock Hospital, Dean-street, W. Afternoon course in venereal diseases. *Courses arranged by the Fellowship are open only to members and associates.*

WEST LONDON HOSPITAL POST-GRADUATE COLLEGE, Hammersmith, W.

Monday, May 27th.—10 A.M., Medical Wards, Skin Clinic. 11 A.M., Surgical Wards. 2 P.M., Surgical and Gynæcological Wards, Eye and Gynæcological Clinics. 4.15 P.M., Mr. Green-Armytage: Seven Obstetric Pillars.

Tuesday.—10 A.M., Medical Wards. 11 A.M., Surgical Wards. 2 P.M., Throat Clinic. 4.15 P.M. Dr. Redvers Ironside: Diseases of the Sympathetic Nervous System.

Wednesday.—10 A.M., Medical and Children's Wards, Children's Clinic. 2 P.M., Eye Clinic, Gynæcological Operations.

Thursday.—10 A.M. [illegible] Gynæcological Clinics. Noon, [illegible] y and Eye Clinics [illegible]

Friday.—10 A.M., S[illegible] t., 2 P.M., Throat [illegible]: Lecture.

Saturday, June 1st.—10 A.M., Surgical and Children's Clinics, Medical Wards.

Daily at 2 P.M., Operations, Medical and Surgical Clinics. *The lectures at 4.15 P.M. are open to all medical practitioners without fee.*

SOUTH-WEST LONDON POST-GRADUATE ASSOCIATION, St. James' Hospital, Ouseley-road, S.W.

Wednesday, May 29th.—4 P.M., Dr. W. J. O'Donovan: Skin Diseases and the Workmen's Compensation Act.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C.

Thursday, May 30th.—2 P.M., Dr. W. J. Pearson: Pulmonary Tuberculosis. 3 P.M., Dr. W. W. Payne: Carbohydrate Metabolism: 2. Action of Insulin.

Out-patient Clinics daily at 10 A.M. and Ward Visits (except Wednesday) at 2 P.M.

UNIVERSITY OF LONDON.

Monday, May 27th, Wednesday and Friday.—*5.30 P.M.* (University College), Prof. William McDougall, F.R.S.: Psychoanalysis and Social Psychology.

Tuesday, Thursday, and Friday.—5.30 P.M. (King's College, Strand, W.C.), Dr. Daniel De Lange: The Head Problem in Chordates.

NATIONAL INSTITUTE OF INDUSTRIAL PSYCHOLOGY.

Monday, May 27th.—5.30 P.M. (London School of Hygiene and Tropical Medicine, Keppel-street, W.C.), Miss May Smith, D.Sc.: Temperamental Factor in Industry. (Last of three lectures.)

INSTITUTE OF MEDICAL PSYCHOLOGY, Malet-place, W.C.

Wednesday, May 29th.—3 P.M., Dr. H. Crichton-Miller: Toxic Neurasthenia. 4.30 P.M., Dr. Cedric Shaw: Gastro-intestinal Syndromes.

LONDON SCHOOL OF DERMATOLOGY, 49, Leicester-square, W.C.

Monday, May 27th.—5 P.M., Dr. M. Sydney Thomson: Common Skin Diseases in Childhood.

Tuesday.—5 P.M., Dr. H. W. Barber: Alopecia Areata, and Vitiligo.

Wednesday.—5 P.M., Dr. J. A. Drake: Animal Parasites.

Thursday.—5 P.M., Dr. A. M. H. Gray: Sclerodermia and Allied Conditions.

INSTITUTE OF PATHOLOGY AND RESEARCH, St. Mary's Hospital, W.2.

Thursday, May 30th.—5 P.M., Dr. Ronald Canti: Cultivation of Living Tissue.

ROYAL INFIRMARY, Manchester.

Tuesday, May 28th.—4.15 P.M., Dr. J. F. Wilkinson: Anæmia.

Friday.—4.15 P.M., Dr. T. H. Oliver: Demonstration of Medical Cases.

UNIVERSITY OF BIRMINGHAM[illegible]

Tuesday, Ma[illegible] ral Hospital), Mr. F. A. R. [illegible] of Surgical Cases.

Friday, May [illegible] Hospital), Dr. O. Brenner: [illegible] Heart Disease.

UNIVERSITY OF DURHAM COLLEGE OF MEDICINE.

Sunday, May 26th.—10.30 A.M. (Newcastle General Hospital), Prof. T. Beattie: Medical Ward Visit.

ROYAL INFIRMARY, Dundee.

Thursday, May 30th.—3.15 P.M., Mr. F. R. Brown: Surgery of the Sympathetic Nervous System. 4.15 P.M., Prof. Charteris: Recent Advances in Therapy which are likely to prove important.

GLASGOW POST-GRADUATE MEDICAL ASSOCIATION.

Wednesday, June 29th.—4.15 P.M. (Eye Infirmary), Dr. A. J. Ballantyne and Dr. S. Spence Meighan: Eye Cases.

Appointments

Burnham, Cecil, M.B., F.R.C.S. Edin., has been appointed Hon. Surgeon to the London Homœopathic Hospital.

Don, C. S. D., M.D. Aberd., M.R.C.P. Lond., Hon. Assistant Physician to [illegible] nary.

Ellison, J. E., M[illegible] Resident Surgical Officer at the [illegible]

Ironside, R. N., [illegible], Hon. Assistant Physician to [illegible] and Paralysis, Maida Vale.

***Russell, A. S. Dill**, M.B. Lond., Second Anæsthetist, London* Lock Hospital.

Smyth, Michael, M.Ch. Irel., F.R.C.S. Eng., Hon. Assistant Surgeon to the London Homœopathic Hospital.

Townsley, N. J., M.B. Belf., Resident Surgical Officer at the Royal Manchester Children's Hospital.

Births, Marriages, and Deaths

BIRTHS

Crouch.—On May 15th, at Welbeck-street, *the wife of H. A.* Crouch, O.B.E., M.C., M.R.C.S. Eng., Sudan Medical Service, of a son.

Durno.—On May 15th, at Herne Hill, S.E., the wife of J. Fyvie Durno, M.B. Aberd., of a daughter.

Evans.—On May 12th, at Devonshire-place, the wife of E. Stanley Evans, F.R.C.S. Eng., of Ascot, Berks, of a son.

Flood.—On May 16th, at Limpsfield, Surrey, the wife of Phillip Flood, M.R.C.S. Eng., of a daughter.

Graham Bryce.—On May 13th, at Didsbury, Manchester, the wife of Alexander Graham Bryce, F.R.C.S. Eng., of a son.

Grose.—*On May 20th*, at Suffolk House, Stanmore, to Winifred (*née* Oliver), wife [illegible] vare, of a son.

Maclean.—On May [illegible] the wife of Donald Maclean, [illegible] of a son.

Welch.—On May 12t[illegible] near Bedford, the wife of Cuth[illegible] Lond., of a daughter.

MARRIAGES

Bromley—Aveling.—On *May 18th*, at *All Saints'* Church, Wetheringsett, Suffolk, James Wilfred Bromley, M.B. Camb., to Elizabeth, only daughter of Dr. L. B. Aveling, of Brockford, near Stowmarket.

DEATHS

Brittain.—On May 18th, Percy Morgan Brittain, L.M.S.S.A., of Hatfield, Herts.

Ewens.—On May 13th, at Eastbourne, Henry Luther Ewens, M.D. Durh., aged 68 years.

Harper.—On May 18th, Peter Harper, M.D. Aberd., of Ferme Park-road, Hornsey, N.

Scott.—On April 1st, at Melbourne, Bernard Charles Scott, M.R.C.S. Eng., eldest son of the late Rev. T. S. Scott, Vicar of Anerley, aged 74.

Wilson.—On May 19th, suddenly, at Romford-road, Manor Park, Essex, William Alexander Wilson, M.B., Ch.B. Glasg., aged 52.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

NOTES, COMMENTS, AND ABSTRACTS

THE INFLUENCE OF FOOD ON CHILD-BEARING *

By V. B. Green-Armytage, M.D. Brist.,
F.R.C.P. Lond., F.C.O.G.
GYNÆCOLOGICAL SURGEON TO THE WEST LONDON HOSPITAL, AND OBSTETRIC SURGEON, JEWISH MATERNITY HOSPITAL

More and more during recent years has it become manifest that the empirical knowledge and deductions of our forefathers were founded on sound scientific principles. For instance, take the recent work of biochemists, and particularly of Macomber, upon the physico-chemistry of sterility and abortion. It has been shown that vitamins E, A, and D are essential, and exist in every well-balanced diet because Nature is primarily concerned in the art of creation. It is therefore not without interest to read in the Books of Kings and Samuel no mean table of foodstuffs to remove what in the Bible is called "this reproach among men"; the diet recommended consisting of "wheat, barley, and meal, parched corn, beans, lentils, olives, honey, butter, sheep, and cheese of kine, with fatted fowl and fatted oxen and all the fruits of the field."

Moreover, we find in the Old Testament the first classical example of suggestion, coincidence, or enviable practice in the treatment of sterility, for we read "and Reuben, going out at the time of the wheat harvest found mandrakes which he brought to his mother Leah, and Jacob slept with Leah that night and she conceived, and later also Rachael conceived." The mandrake contains vitamin E and is our *Mandragora autumnalis*, which belongs to the solanaceæ and is an antispasmodic.

To some, such inference may appear fantastic; but I can assure them that many a time, both here and in the East, I have found that if you can correct the diet, either directly in the home or by change of scene, and will, at the same time, speed up metabolic "revs" (to use a mechanical term) by giving small doses of thyroid gland and iodine solution to both husband and wife for three months at least, your patient will become pregnant and remain so without abortion.

The exact mechanism we know not. My own view is that the thyroid speeds up every gland of internal secretion, and particularly the endometrium and chorion, which is thereby enabled to filter, or neutralise the effect of toxins or secretions which disturb carbohydrate metabolism, causing hypoglycæmia with decrease of the alkalinity of the blood and increase of blood pressure, damage to the renal glomeruli and hepatic lobules arising later with or without convulsions.

Time will show; but I think the pendulum of opinion is swinging towards the conclusion that the so-called toxæmia of pregnancy is primarily a pluriglandular endocrinal upset, and that most of the symptoms are due to toxins from the bowel which primarily injure the hypophysis. Hitherto the placenta has borne the brunt of blame.

Calcium

Much has been written in recent years of the calcium phosphorus content, and rightly so, for every fœtus is a parasite battening upon its mother for the formation of bone and teeth, &c. Indeed, dental calcification begins as early as the seventeenth week, but Nature prepares for this by commencing the formation of the fœtal thyroid and parathyroids about the twelfth week, their duty being the maintenance and control of calcium metabolism.

Abroad I have seen countless times during pregnancy, patients on the lowest rungs of the calcium-phosphorus ladder, representing osteomalacia, tetany, and fœtal rickets, whereas in England one encounters cases on the middle or higher rungs which, because not thought of, are not so easy to diagnose. Minor degrees of pregnancy acalcæmia are ever with us in this great city. In some, the main stress is in youth, the back and pelvic girdle showing it in the form of scoliosis, lordosis, and descent of the promontory. If such women marry, delivery may demand surgical assistance or necessitate mutilative operations. In others, without any symptoms whatever, owing to softness of the bones and the weight of the body, at the second dentition or puberty, the pelvis may assume the android or funnel type, with lessening of the sub-pubic angle and great contraction of the outlet.

Let me recall the case of a patient who went from Bradford to marry in India. To all appearances she was a strong, strapping, Yorkshire girl. She went into labour. Her doctor was quite comfortable as regards her usual measurements and the relation of the fœtal head to the inlet; but he forgot—or perhaps it would be better to say he had not been taught—to pay attention to the outlet measurement. After the head had been on the perineum for some hours, he tried to apply forceps and could not. He then did a craniotomy. She developed puerperal septicæmia and was sent to my isolation block, where she died. Had she been measured, or had it been realised that a diet deficient in youth can produce symptomless bony deformity at the outlet only, this disaster could have been avoided by Cæsarean section.

Take another condition as common in private as in hospital practice—the flabby uterine wall associated, with a flabby abdominal wall and flabby cardiac wall. Here we have a condition producing a syndrome of peculiar risk—namely, malpresentation, uterine inertia, retained placenta, post-partum hæmorrhage, and obstetric shock. (I do not include inversion, because it is so rare.)

Any or all of these may be found in the anæmic, acalcæmic woman who has been watched through pregnancy with an unseeing eye; for "without vision the people perish."

Endocrine Factors

It is one of the paradoxes of Nature that it is the multipara who suffers most. They are not often like the well-fed Hebrew women, in the book of Exodus—"brisk creatures delivered before ever a midwife reaches them" (Moffatt)—but are like the wife of Phinehas in the book of Samuel, who big with child bowed herself and fell in labour; and when she was on the point of death they that stood about her said, "Fear not for thou hast born a son. But she answered not, neither did she regard it." These are signs and symptoms of clinical importance which compel attention and drive home the maxim that the "vitamins are to the endocrines what the endocrines are to the economy"; for by correct feeding, sunshine, and exercise, disaster may be obviated.

Modern biochemistry and the pathology of the living indicate that many of the tragedies of pregnancy are due to deficiency or excess of the endocrine glands associated with dietetic errors. For a long while we have known that the thyroid gland hypertrophies, and now we know that the adrenals and pituitary do likewise, obviously for the maintenance of equilibrium. If, however, normal metabolic function should be disturbed, glandular dystrophy will manifest itself. For instance, excess of posterior pituitary secretion, associated with imbalance of the thyroid and parathyroids, causes hæmorrhages, hyperexcitability, high blood pressure and flabby uterine wall, flabby heart wall, and hyperglycæmia.

The whole subject is one of intense interest, and it is the close relation of the endocrine system to the food intake that makes antenatal care so important, because only by keeping this view constantly in mind are we able to detect any deviation from the normal as regards blood pressure, urine, reflexes, and blood changes. The trend of modern opinion being that such substances as guanidine, histamine, and/or histidine (the breakdown products of vitiated function) are absorbed and give rise to their effects via the endocrine system. It is probable that this view is not far-fetched, for anyone who has ever seen a case of colubrine snake poisoning will agree that the effects of such injected poison are similar to those of the toxæmia of pregnancy. Such effects as hypoglycæmia, the increase of blood ketones and amines, the rise in blood pressure, the cyanosis, the œdema, the renohepatic damage and, finally, the convulsions, could not occur so rapidly unless the poison acted through or upon the pituitary gland.

---

* A post-graduate opening address delivered at the West London Hospital on March 11th.

I am perfectly aware that there is a tendency to overdo antenatal care, but while modern urban life is so far removed from Nature and while coroners and newspapers and, what Shakespeare called "long-tongued, babbling gossips," exist, it is better to be careful rather than careless. Moreover, for those who deride, it is interesting to remember that so long ago as Genesis, the hyperexcitability of acalcæmia and hypothyroidism in the primipara was observed; for it is written that "Isaac besought the Lord for his wife because she was barren and He heard him. And after a time the children struggled in her womb and she was afraid and said, 'If it were to be so with me what need is there to conceive.'" Even in those days, therefore, tumultuous movements of the fœtus, usually associated with hypoglycæmia and lack of calcium, were known to anticipate miscarriage or premature delivery. Just as to-day we recognise that deficiency of vitamin D and C in the diet, and consequent deficiency of calcium and phosphorus during pregnancy, spell gingivitis, dental caries, muscular weakness, spasmodic cramps in the legs or arms, tachycardia, and tetany. Moreover, time will probably show that diet and pluriglandular dystrophy are associated with, or responsible for, diminution of the folliculin-producing principle in the ovary and placenta, which controls spontaneous contraction and the termination of gestation, and thereby lead in some cases to prematurity or pathological post-maturity.

Anæmia

So far, I have endeavoured to present a reasonable explanation for some of the major disabilities of pregnancy and parturition and have tried to show how many of the tragedies of childbearing are bound up with the abuse of natural food, and urban methods of living—Providence hurling the thunderbolt when endocrine function reaches its limit.

It now remains for us to deal with a lesser but no less important condition—that of the anæmias of pregnancy.

There are six different groups of anæmia of pregnancy, but I need not speak of those types which are associated with hæmolytic streptococci in the blood, or of that which is the sequence of postpartum hæmorrhage, or of that large group which is accompanied by disease of the spleen, lymph-glands, or marrow. But rather I want to remind you of those three common groups which are frequently met in practice.

The first is not very serious and is a condition of hydræmia which is associated with mild anæmia and œdema of the limbs and is due to the fact that the food supply is insufficient in those substances which equilibrilise the normal strain of pregnancy—substances which are found in all good diets—namely, calcium, iron, manganese, and copper. These cases are readily curable.

The second type is more insidious and is often met with in cases where there has been vomiting and much constipation in the early months and where the diet has long been poor, or is at the moment deficient, in those specific substances necessary for hæmopoiesis—namely, protein, fruits, and green vegetables. Moreover, it has been shown by Castle that these women have hypochlorhydria or achlorhydria accompanied with reduction or inactivity of the gastric enzyme. A blood picture shows hypochromia with marked reduction in hæmoglobin but a less marked diminution of red blood-cells. The red cells are small and vary in shape. Normoblasts may be present but megalocytes are not seen. There is a slight relative leucocytosis. If treatment is not actively instituted these changes rapidly progress and are accompanied by great prostration, dyspnœa, and œdema. Albuminuria is occasionally present and in the untreated patient miscarriage is by no means uncommon.

It used to be thought that this progressive anæmia was due to a placental toxin or bone-marrow disease, but now that we know that there is a reduction in the free HCl and total acidity of the gastric juice we realise that this type of anæmia is due to a diminution of hæmoglobin-building materials in the food together with a lessened ability to utilise such materials after ingestion. Moreover, when it is remembered that every fœtus in utero is a parasite, and in this particular type of case is born at term with a normal blood count and a liver fully stored with iron, copper, zinc, and so on, it will be understood that the demand of the fœtus for such hæmoglobin-building materials has been at the expense of its parent and is exactly comparable in its effect upon the hypochlorhydric mother, as visible and repeated blood losses would be. This being so, the outlook is good provided the clinical condition has been early recognised, for the treatment is mainly by sunlight, diet, and the provision of food containing those intrinsic and extrinsic factors in proteins, vegetables, and fruits, which stimulate hæmopoiesis. Liver in some form being also essential. Iron is given in the form of fresh Blaud's mass, grs. 90 per day, together with well-diluted hydrochloric acid.

The last type is the most grave from the patient's and practitioner's point of view and resembles Addison's pernicious anæmia. It is due to deficiency of Castle's extrinsic factor in the diet or lack of his intrinsic hæmatinic principle in the stomach and intestine. These patients have a waxy appearance and often there is a daily rise of fever and enlargement of the spleen which may simulate typhoid. The tongue is sore and in some patients retinal changes occur. Œdema and albuminuria are often present but rarely is there hypochlorhydria or achlorhydria. The blood picture shows a colour-index above 1 and much variation in the shape and size of the red blood-cells. Megalocytes are always present which means a pathological proliferation of megaloblasts in the bone marrow.

This type of anæmia is rare in England, but may be seen in patients who have come from the tropics to reside in London; for megalocytic anæmia is extremely common in the tropics and frequently accompanies sprue, dysentery, or parasitic infections of the bowel.

During pregnancy, or immediately after it, this type of anæmia may be fatal if it has not been recognised and treated adequately. Fortunately for us and the people of the tropics, the brilliant research work of Miss Lucy Wills has given us almost a specific method of treatment; for she has shown that whereas many of these cases react excellently to liver-ventriculin treatment on the intrinsic principle of Castle, others fail to do so because they lack that extrinsic factor (vitamin-B complex) in their diet which stimulates reticulocyte response. Such response can be assured and recovery made certain by giving Marmite ½ *to 1 oz.* per diem in addition to the usual dietetic measures, with or without repeated small blood transfusions. Marmite is an autolysed extract made from brewer's yeast and is probably a protein breakdown product.

The Useful Foods

So far I have spoken much of diet but have given no detail. Perhaps, therefore, I may be permitted to enumerate those food substances which particularly contain iron, copper, and manganese, together with the vitamins A, B, C, D, and E. They are: Asparagus, almonds, beef (lean), beans (kidney), barley, carrots, cheese, eggs (yolk), green vegetables (especially lettuce and spinach), liver, oatmeal, oysters, peas, peanuts, potatoes, prunes, raisins, walnuts, and wheat. Milk and fruit, such as apples, bananas, oranges, and grape-fruit, contrary to the general lay view, contain these metals in infinitesimal quantities. One pint of good raw milk contains 10 grains of calcium and nearly an ounce each of fat and protein, and 7 ounces of fresh protein contains 3 grains of calcium only. But every fœtus after the fifth month needs that quantity of calcium per day. So the mother must eat for two in order to maintain her calcium balance and mineral needs.

Here I should like to refer to the importance of Prof. E. Mellanby's work in the prevention of puerperal sepsis. As you know, by experiment in the septic isolation block at Sheffield, he was able to demonstrate that the concentrated exhibition of vitamin A preparations was capable of diminishing the mortality in septicæmia. This observation has not been fully corroborated, but there seems little doubt that if the antenatal patient is fed properly with foodstuffs or preparations containing vitamin A, she is less likely to develop septic complications after labour, the probability being that vitamin A is provided in food by Nature, to raise the resistance or surface tension of the epithelium to invasion by organisms. My own experience fully bears this out and I am sure that practitioners who often have to work under conditions far from ideal, would do well, not only to diet, but throughout pregnancy to prescribe one of the many vitamin A and D preparations on the market.

Finally, let me say something of the importance of diet in the postnatal period; for quite apart from its importance to the nursing mother and infant, we must remember that involution and repair has to occur in the muscles, bones, and joints, as well as in the uterus. Many of the postnatal aches and pains in the back and pelvic girdle are due to continued laxity of ligaments and cartilage which should not persist. Many of these symptoms are due to the fact that the fœtus is still draining the mother of calcium, phosphorus, &c., which she should make good in her diet; but it is more than probable that in many cases from poverty, lack of sunshine, and debility, the mother is incapable of doing this.

It is possible that many cases of one-child sterility are due to the mother remaining an invalid on a deficient diet after pregnancy; the defect in minerals reacting upon the hypophysis and ovary.

COMMITTEE AGAINST MALNUTRITION

At a public meeting held in London on May 16th, under the auspices of this committee, Prof. V. H. Mottram, who presided, remarked that people seem to think that malnutrition is a definite state, whereas he would suggest that any nutrition falling below the optimum is malnutrition. Mr. Joseph Needham, D.Sc., reader in biochemistry in the University of Cambridge, mentioned investigations which showed that, whereas a group of good-class public school-children gave 50 per cent. as in the highest category for health, a poor elementary school gave only 9·6 per cent., and an elementary school in an area with severe unemployment 6 per cent. A further inquiry had shown that a group of public school boys were on the average 20 lb. heavier than a group of boys of the same age in poor schools. Miss Eleanor Rathbone, M.P., contended that it was unfair to place upon the working housewife the responsibility for malnutrition: that her "ignorance" played but a small part was shown in recent surveys—e.g., on Merseyside. If the working housewife spent little on milk, vegetables, and fruit, it was because she could not afford it. In the maldistribution of wealth unfair taxation played a part; again, wages and salaries took no account of family responsibilities. There was now, said Miss Rathbone, an opportunity of making two needs fit into each other—the need of the ill-fed and the need of the agricultural industry. About three million school-children now received a third of a pint of milk cheap on school days. If more money were granted, this service could be extended to the other three million school-children (not only on school days but on holidays as well) and to the children under school age and their mothers. She believed also that there was a strong case for providing one free meal a day for all elementary school-children, and to all secondary school-children under a suitable means test. Dr. Janet Vaughan said that half the patients that came to her out-patients' clinic suffered from diseases which could have been prevented if they had had the right food. There was a campaign for curing "incurable" diseases like cancer; why not a campaign for curing the diseases for which the cure was known, the deficiency diseases? Dr. J. R. Marrack, university professor of chemical pathology at the London Hospital, spoke of diseases not directly but indirectly due to inadequate food. Children with rickets, for example, were more likely to die from pneumonia, whooping-cough, and bronchitis—the main causes of death among young children—while from anæmia one would find increased incidences of other diseases such as pneumonia and diarrhœa. The increase of tuberculosis in neutral countries during the late war could only, in his opinion, be accounted for by food deficiencies. Leprosy in some parts of India attacked 12 per cent. of the people; and there was now little doubt that leprosy was closely associated with food deficiency. Prof. Marrack mentioned that the tuberculosis death-rate among young women between 20 and 30 in Calcutta was nearly as high as the total death-rate in New Zealand from all causes.

NEW PREPARATIONS

Staphylococcus Toxoid A and B.—We have received from Messrs. Burroughs Wellcome and Co., Snow Hill-buildings, London, E.C., samples of two preparations to be used for active immunisation: "Wellcome" Brand Staphylococcus Toxoid A (1/10 dilution), and Staphylococcus Toxoid B (undiluted toxoid), each in containers of 1 c.cm. Immunisation with staphylococcus toxoid has been used recently as a combined method of prophylaxis against, and treatment of, chronic infections. Promising results have been reported from Melbourne and Toronto in such conditions as recurring boils, carbuncles, acne, sycosis, and blepharitis. English experience appears to be not yet large, but the results, obtained mainly during the course of an investigation by the Therapeutic Trials Committee of the Medical Research Council, agree with those reported from Australia and Canada. The investigation of the M.R.C. Committee was carried out with staphylococcus toxoid supplied by the Wellcome Physiological Research Laboratories. In a considerable number of patients "cure" has been obtained; in many "improvement"; and in a small number "no improvement." There are on record, it is frankly admitted, instances of puzzling relapses in patients who had shown rapid disappearance of long-standing symptoms—a phenomenon which further experience may explain and perhaps obviate.

Progestin (B.D.H.).—The corpus luteum secretes a hormone, progestin, the secretion being responsible for the control of many of the phenomena of pregnancy and menstruation. We have received from British Drug Houses Ltd. (Graham-street, City-road, London, N.) a sample of progestin distributed by the firm. Progestin (B.D.H.) is a preparation of the hormone standardised for its proliferational activity in the immature rabbit uterus previously treated with œstrin. The manufacturers have evidence that it should be of value especially in the functional disorders of pregnancy and menstruation. The drug is to be injected intramuscularly, for which purpose it is issued in ampoules, the contents of which may be found on examination to be turbid. This turbidity can be removed by warming, and in all events it is recommended to place the ampoule in warm water before transferring the contents to a syringe, which should have a strong needle, at least 2 in. in length and of sufficient diameter to allow free passage of the oily solution. A circular issued by the firm with the preparation claims that complete absence of menstruation or a scanty menstrual flow may be treated with advantage with a mixture of œstrin and the corpus luteum hormone.

FERRO-"HEPAMULT."—Messrs. H. R. Napp Ltd., 3 and 4, Clements-inn, London, W.C., send us a brochure in explanation of their new product Ferro-"Hepamult," together with a sample of the preparation. This consists of the active principles of liver, which last year the firm introduced to the medical profession under the name "Hepamult" (v. THE LANCET, 1934, ii., 342), together with an assimilable ferrous salt. It is standardised in the proportion of 10 g. "Hepamult" (equals 8 oz. fresh liver) to 1·7 g. iron, that quantity being the average daily dose. Ferro-"Hepamult" is intended for the treatment of anæmias, and should find favour with practitioners, as a combination of liver and iron treatment in anæmic conditions is very generally recognised as valuable. Ferro-"Hepamult" is presented in the form of palatable sugar-coated granules carefully tested and standardised, while the iron content is in the form of a stable ferrous salt ensuring ready absorption and absence of intestinal irritation.

BENGAL MEDICAL COLLEGE CENTENARY VOLUME.—This may be obtained from the secretary of the subcommittee, Dr. A. C. Ukil, Medical College, Calcutta.

Vacancies

For further information refer to the advertisement columns

Aberdeen Royal Infirmary.—Two Hon. Clin. Tutors.

Accrington, Victoria Hospital.—H.S. £150.

Albert Dock Hospital, Connaught-road, S.E.—Res. M.O. At rate of £110.

All Saints' Hospital, Austral-street, S.E.—Res. H.S. At rate of £100.

Bath, Royal United Hospital.—Hon. Surg. for Ear, Nose, and Throat Dept., and Hon. Med. Reg.

Beckenham, Bethlem Royal Hospital, Monks Orchard.—Radiologist. 150 guineas.

Bedford County Hospital.—First and Second H.S. At rate of £155 and

Belfast, Royal M.O. At rate of £26.

Physician. £650.

Each £125.

for Consumption, &c.—

Sanatorium.—Asst Res. M.O. £175.

Brentwood, Essex County Mental Hospital.—Jun. Asst. M.O. £510.

Brighton, Royal Alexandra Hospital for Sick Children.—H.S. £120.

Cancer Hospital, Fulham-road, S.W.—H.S. At rate of £100.

Canterbury, Kent and Canterbury Hospital.—Two H.S.'s. Each at rate of £125.

Carshalton, &c., District Hospital.—Two Hon. M.O.'s.

Charing Cross Hospital, W.C.—Asst. Physician.

Chelsea Hospital for Women, Arthur-street, S.W.—Jun. H.S. At rate of £100.

Cheltenham General and Eye Hospitals.—H.P. £200.

Connaught Hospital, Walthamstow, E.—H.S. At rate of £100.

Coventry and Warwickshire Hospital.—H.S. for Aural and Ophth. Depts. At rate of £125.

Downpatrick, Down Mental Hospital.—Res. Med. Supt. £800. Also Asst. M.O. £350.

Dreadnought Hospital, Greenwich.—Hon. Gynæcologist. Also H.P. and H.S. Each at rate of £110.

Elizabeth Garrett Anderson Hospital, Euston-road, N.W.—Clin. Asst. to Ear, Nose, and Throat Dept. Also H.P., three H.S.'s, and Obstet. Asst. Each at rate of £50.

Evelina Hospital for Sick Children, Southwark, S.E.—H.P. At rate of £120.

Gateshead Mental Hospital.—Med. Supt. £800. Also Asst. M.O. £400.

Glasgow University.—St. Mungo Chair of Surgery.

Hartlepools Hospital.—H.S. At rate of £150.

Hastings, Royal East Sussex Hospital.—Jun. H.S. At rate of £150.

Hertford County Hospital.—Sen. H.S. At rate of £200.

Hospital for Consumption and Diseases of the Chest, Brompton, S.W.—Asst. for Dept. of Pathology. £350. Also Asst. Physician.

Hospital for Tropical Diseases, Gordon-street, W.C.—Two H.P.'s. Each at rate of £120.

Hospital for Women, Soho-square, W.—Res. M.O. At rate of £100.

Hove, Lady Chichester Hospital.—Jun. H.P. At rate of £50.

t rate of £150.

sions.

vich Hospital.—H.P. £120.

Each £100–£120 per mensem.

r Law Infirmary.—Res. M.O. £100–£200.

King George Hospital, Ilford.—Res. Surg. O. and Res. Asst. Surg. O. £300 and £250 respectively. Also Two H.P.'s and Three H.S.'s. Each at rate of £100.

Leicester Royal Infirmary.—H.S. At rate of £125.

Leicestershire and Rutland Mental Hospital, Narborough.—Asst. M.O. £350.

Liverpool, Stanley Hospital.—Hon. Asst. Surgeon.

London Hospital, E.—Physician. Also Surgeon.

Lucknow University.—Prof. of Medicine. Rs.900/- per mensem.

Macclesfield General Infirmary.—Second H.S. At rate of £150.

Maidstone, West Kent General Hospital.—H.S. £150.

Manchester Ear Hospital.—Res. H.S. £120.

Manchester Royal Infirmary.—Res. Clin. Pathologist. £100.

Metropolitan Water Board, Rosebery-avenue, E.C.—Chief M.O.

Middlesbrough, North Riding Infirmary.—Third H.S. At rate of £125.

Mid-Wales Counties Mental Hospital, Talgarth, Breconshire.—Asst. M.O. £400.

ria Infirmary, &c.—Temp. Asst.

0–£600.

Mental Hospital.—Clin. Asst. 30 guineas.

Norwich City.—Asst. M.O.H. and Asst. School M.O. £500.

Paddington Hospital, Harrow-road, W.—Res. Med. Supt. £1100.

Preston, Sharoe Green Hospital.—Sen. Asst. Res. M.O. At rate of £150.

Princess Elizabeth of York Hospital for Children, E.—H.P. and H.S. Each at rate of £125.

Queen Charlotte's Maternity Hospital, Marylebone-road, N.W.—Registrar. 20 guineas.

Queen Mary's Hospital for the East End, E.—Res. M.O. and Two Cas. O.'s. Each £150. Also Two H.S.'s., H.P., Obstet. H.S., and Res. Anæsthetist. Each £120.

Queen's Hospital for Children, Hackney-road, E.—H.P. and Cas. O. Each at rate of £100.

Romilly Lodge for Mentally Defectives, Hornsey Rise, N.—Part-time M.O. At rate of £40.

Ross Institute of Tropical Hygiene, Keppel-street, W.—M.O.'s.

Royal College of Physicians of London.—Leverhulme Research Scholarship. £500.

Royal Free Hospital, Gray's Inn-road, W.C.—Res. Cas. O. At rate of £150. Also First H.S. and Res. Anæsthetist.

Royal Masonic Hospital, Ravenscourt Park, W.—Res. Surg. O. At rate of £250.

Royal Waterloo Hospital for Children and Women, Waterloo-road, S.E.—Cas. O. £200. Also H.S. At rate of £100.

Ryde, Royal Isle of Wight County Hospital.—Res. H.S. At rate of £180.

St. George's Hospital, S.W.—Asst. Physician.

Salvation Army, Mother's Hospital, Lower Clapton-road, N.—Jun. Res. M.O. At rate of £80.

Sheffield, Jessop Hospital for Women.—Three H.S.'s. Each at rate of £100.

Sheffield Royal Hospital.—Clin. Asst. to Ear, Nose, and Throat Dept. £300.

Sheffield Royal Infirmary and Royal Hospital.—Clin. Asst. £300.

Sheffield University.—Asst. Pathologist and Demonstrator. £500. Also Lecturer in Bacteriology. £600.

Southend-on-Sea General Hospital.—Med. Reg. £300. Surg. Reg. £250.

Stockport Infirmary.—Res. Surg. O. £250.

Surrey County Council.—Two Asst. M.O.'s. Each £600.

Warwick, King Edward VII. Memorial Sanatorium, Hertford-hill. Jun. Asst. M.O. At rate of £200.

Watford and District Peace Memorial Hospital.—H.S. At rate of £150.

West Bromwich and District General Hospital.—H.P. At rate of £200.

West London Hospital, Hammersmith-road, W.—Chief Clin. Asst. in X Ray Dept. £125. Cas. O. £250. Also H.P. and 2 H.S.'s. Each at rate of £100.

Winchester, Royal Hampshire County Hospital.—H.S. At rate of £125.

Wolverhampton and Midland Counties Eye Infirmary.—H.S. £150.

Worksop, Victoria Hospital.—Two Residents. At rate of £150 and £120 respectively.

The Chief Inspector of Factories announces a vacancy for a Certifying Factory Surgeon at Castle Hedingham, Essex.

Medical Referee under the Workmen's Compensation Act, 1925, for the Ashby-de-la-Zouch and Loughborough County Court Districts (Circuit No. 20). Applications should be addressed to the Private Secretary, Home Office, Whitehall, London, S.W.1, before June 12th.

CHISWICK GENERAL HOSPITAL.—The old house on Chiswick Mall, which the late Mr. Dan Mason gave to be used as Chiswick Hospital, is to be demolished and a new hospital is to be erected on the same site. No appeal will be made to the public for funds for rebuilding, and there will be accommodation for 14 men, 14 women, and 10 children.

ADDRESSES AND ORIGINAL ARTICLES

OBSERVATIONS ON THE ABDOMINAL AND CIRCULATORY PHENOMENA OF ALLERGY

BY JOHN A. RYLE, M.D., F.R.C.P. Lond.
PHYSICIAN TO GUY'S HOSPITAL

IN recent times attempts have been made to spread the net of allergy too widely. Conditions having no clinical or ætiological relationships with the accepted allergic disorders have been discussed as possible or probable examples of these disorders. It is a primary duty of clinical study to define disease, to render descriptions more precise, and to establish diagnostic criteria. At present we include among the allergic disorders asthma, hay-fever, spasmodic rhinorrhœa, intermittent hydrarthrosis, urticaria, angioneurotic œdema, and eczema. With regard to migraine and epilepsy, although they appear not infrequently in persons and families subject to allergy and the former may be associated with food idiosyncrasies, opinion is less secure. A paroxysmal neurosis, although it consorts with "nervous" constitutions and develops in response to minimal stimuli, need not necessarily depend upon that type of idiosyncrasy which allergy implies. Activation of symptoms by anxiety or an east wind would not at present be considered as evidence of allergy. Certain gastro-intestinal disorders and circulatory phenomena have also been classified as allergic, but they stand in need of more careful portraiture.

It is the purpose of this paper to identify and define certain abdominal syndromes and circulatory disturbances which may be reasonably regarded as expressions of the allergic state and, on a purely clinical basis, to suggest criteria without which we should be unwilling to accept them as genuinely allergic.

Allergy and Anaphylaxis

The word allergy has not found its way into the Shorter Oxford Dictionary. In Dorland's Medical Dictionary it is described as "a condition of altered susceptibility which causes an individual to react to a second inoculation of an antigen in a manner different from his reaction to the first inoculation (von Pirquet). The term is now used to denote the natural hypersensitiveness of an individual as contrasted with anaphylaxis, which is hypersensitiveness artificially induced by inoculation." The clinical relationships of anaphylaxis and allergy are, however, very close. Identical symptoms occur in the artificially induced and the spontaneously developed disorder. Main distinctions between the two conditions are that anaphylaxis depends upon a specific sensitisation and has a limited course, whereas in allergic states precise specificity is rare or other forms of sensitiveness become superimposed upon an original form, while nervous reproduction of symptoms is readily conditioned. Cases of pure horse-asthma, for instance, are exceptional and in most asthmatics there is a multiplicity of circumstances which may condition or predispose to the attack. Furthermore the clinical course of an allergic disorder is recurrent and unlimited.

It would also seem that anaphylactic symptoms, although more readily induced in persons subject to allergic disorders, can be produced in some degree independently of particular constitutional predisposition. Allergy, on the other hand, is expressive of an inborn or constitutional predisposition and for this reason can result from smaller and often infinitesimal or undiscoverable stimuli.

"EXPERIMENTAL DISEASE" IN HUMANS

While serum-sickness is common, opportunities of studying anaphylactic shock in man are fortunately rare. It may baffle observation by proving immediately fatal. Some years ago, in conjunction with J. Fawcett, I wrote a paper entitled "Cases of Delayed and Immediate Anaphylactic Shock with a note on the Circulatory Phenomena."[1] I reproduce our descriptions and discussion of two cases here, together with an account of one other case seen since, for the sole purpose of portraying the "experimental disease" (which includes both serum-sickness and serum-shock), and considering thereafter how far it is possible to discover parallel phenomena in a group of "spontaneous" cases which I have since, after careful consideration, classified in my files under the heading of allergy.

CASE 1. *Delayed Anaphylactic Shock.*—A young woman, aged 23, was admitted into Guy's Hospital under the care of Mr. F. J. Steward on Nov. 5th, 1922, with a "septic" finger. Operations were performed on the 6th, 8th, 10th, and 12th, for spread of infection, amputation of the finger finally becoming necessary. On Nov. 10th 50 c.cm. of antistreptococcal serum were given subcutaneously at the time of operation. Four days later patches of urticaria began to appear, and there was slight evening pyrexia. The local condition after the 12th progressed satisfactorily. At 4.30 A.M. on the 18th, eight days after the serum was given, the patient was wakened by breathlessness. She was seen at 5 A.M. by one of us (J. A. R.) and was then sitting up in bed with "asthmatic" breathing. The respiration-rate was 30 per minute, expiration was prolonged and wheezing, and she was expectorating small quantities of clear mucoid sputum. Sibilant expiratory rhonchi were audible all over the chest. She was pale, and the pulse-rate was between 110 and 120 per minute. Urticaria was appearing in large patches all over the trunk and limbs; the lips, ears, and eyelids were swollen. The house surgeon, Mr. J. K. Milward, had given her an injection of liquor adrenaline 1/1000 ♏ 2. Within 20 minutes the asthmatic attack was over, but she felt cold and shivery, the pulse remained quick, and urticaria continued to appear. She was packed round with hot blankets and bottles, and given hot tea and lactose. She was seen again at 8 A.M. By this time there were no asthmatic symptoms, but urticaria was still troublesome; she had vomited twice, had two actions of the bowels, and was completely pulseless. She complained of feeling "washed out," but apart from the cutaneous irritation and swelling of the gums, made no other specific complaint; she was mentally alert, and quite rational and calm, although she had before been considerably perturbed by the respiratory distress. At 10 A.M. we saw her together; no pulsation could be detected at the wrist or ankle, or in the carotid or subclavian arteries. The heart was not then, or at any subsequent observation, perceptibly enlarged, and there were no murmurs. The impulse was readily felt, the rate was 120–140 per minute, and the sounds were of good quality. She was not cyanosed. She was warm and the temperature was rising. The capillary tide in the nail-bed was good. The question of further administration of adrenaline was discussed, but we were agreed that, with such a degree of tachycardia, and no such urgent indication as "asthma" now persisting, it would be wiser to avoid the possible overstress to the heart which a sudden rise in blood pressure might entail. In spite of her apparently alarming condition a good prognosis was given, partly on the general impression of the patient's demeanour, the rising temperature, and disappearance of the shiveriness of which she had at first complained, and partly on the experience of the other case referred to below. For more than twelve hours no pulse could be felt at the wrist. After twenty-four hours the radial pulse still could not be detected with certainty. Vomiting ceased, but the patient had some nausea and felt that she could not take fluids, except in the smallest quantities, for fear that she would be sick. She was pale and thirsty, had a moist clean tongue, and continued to state that she felt "washed out" and intolerably tired, but that she found difficulty in getting to sleep.

---

[1] THE LANCET, 1923, i., 325.

She was treated throughout with warmth, small quantities of fluid, brandy and lactose by the mouth, and six-hourly rectal administrations of 1 pint of 6 per cent. glucose. The foot of the bed was raised for a few hours, until she complained of the discomfort of the position. Sleep was secured at night with the aid of an opiate. Twenty-eight hours after the onset of the attack the radial pulse could be felt as a doubtful flicker, but not accurately counted. At the cardiac apex the rate could be readily determined as 120 to 130 per minute, but the sounds were not so clear as on the previous day. She now complained of acute pain in nearly all her joints. She could not open the mouth wide on account of pain in the temporo-mandibular joints, and the knees, ankles, wrists, and interphalangeal joints were similarly involved. There was no further trouble with urticaria. Aspirin was added to the rectal injections.

Almost abruptly at about 3 P.M. on the 19th or about 34 hours after the first appearance of urgent symptoms, the pulse became quite good in volume and slower in rate, and from then onwards it improved steadily. By midday on the 20th the pulse-rate was recorded as 80 per minute. After a further forty-eight hours all the joint pains had disappeared, but there was complaint of some deep-seated pain in the muscles of the left thigh. After this her progress was uninterrupted, except for the development of a small patch of erythema below the left knee, and later of an abscess in the right buttock. On the morning of the 18th, when the "shock" symptoms were at their height, the temperature reached 102°, but quickly fell again to normal. It rose during the period of the gluteal abscess, and became stable again after its drainage.

The remarkable feature of this case was the late development of severe shock-like symptoms, true anaphylactic shock being usually considered as an immediate rather than a remote phenomenon. Regarding serum-sickness as the usual anaphylactic response in human subjects, this case might alternatively be viewed as an extreme exaggeration of this response, for the symptoms of "serum-shock" and "serum-sickness" were coincident. Indeed, the case suggests the essential unity of the two conditions. The early development of urticaria, on the fourth day, was perhaps an indication of hypersensitiveness. The patient was not an asthmatic subject, and there was nothing else in her history to indicate that she was previously sensitive to foreign proteins. She had at the time no recollection of ever having had serum before, but it was later elicited from her mother that she had had diphtheria nineteen years previously, and that she was given antitoxin at the time. As there was no history of alarming symptoms on this occasion it would seem proper to regard her illness as a genuine instance of sensitisation by a previous dose. We thought it possible that immediate shock might have been averted by reason of the fact that she was under an anæsthetic at the time of administration of the serum. We were informed by Dr. P. P. Laidlaw that, although anæsthesia may relieve or avert bronchial spasm and so save life in the anaphylactic guinea-pig, it has little effect on similarly induced circulatory shock in dogs.

CASE 2. *Immediate Anaphylactic Shock.*—In October, 1918, a soldier was admitted to a main dressing station with a small wound of the buttock. He was pale, cold, and pulseless; he was vomiting and complaining of abdominal pains. So ill did he appear that special examinations were made to ascertain whether he might have an intra-abdominal lesion with hæmorrhage. The wound was carefully probed and found to be quite superficial. He was not aware of having sustained any other injury. Abdominal examination was negative. Within a short while urticaria appeared, and anaphylactic shock could be confidently diagnosed. The man had during his period of service received two previous prophylactic injections of A.T.S., after one of which he admitted to having "felt bad." He was examined probably within an hour or less of receiving the third dose of A.T.S., which had been given the same evening at an advanced dressing station. Mentally he was perfectly clear. He was treated as an ordinary case of surgical shock by warmth, elevation of the feet, and frequent small sips of fluid, but as after two or three hours the pulse was still impalpable he was sent down to a casualty clearing station with a special note. He there came under the observation of Major G. T. Mullally, who later reported that the man had remained pulseless for some hours, but was fit for evacuation to the base on the following day. Asthmatic symptoms were absent, and gastro-intestinal symptoms were the most prominent apart from those of circulatory failure.

The symptoms in both of the cases described suggested a profound fall in the systemic blood pressure of exceptionally long duration. Presumably the main volume of the blood must have accumulated in the splanchnic area. The absence of œdema and cyanosis, the rapid recovery and maintenance of superficial warmth, and the presence of a good capillary tide in the nail-bed would seem to exclude a capillary stagnation or heart failure. There was no unusual loss of fluid by sweating, diarrhœa, or diuresis, and the fluid intake was well maintained. The symptoms of circulatory shock persisted long after the disappearance of the bronchial, cutaneous, and gastro-intestinal reactions.

Neither before nor since have I seen any condition in which the state of pulselessness manifest in these two cases and persisting for so many hours was consistent with recovery.

CASE 3. *Delayed Anaphylactic Shock.*—A young married woman was operated on for acute appendicitis at 7 P.M. on Nov. 17th, 1932. At the conclusion of the operation she was given an injection of anti-gas-gangrene serum. On the morning of Nov. 23rd I was called urgently to see her with Dr. C. H. Atkinson. After a short period of malaise she had abruptly developed acute anaphylactic symptoms, including generalised urticaria, great œdema of the lips and eyelids, sensations of constriction in the throat, with attendant alarm, profound pallor, and pulselessness. An injection of liq. adrenaline 1/1000 ♏ 3 was given immediately and repeated later. In a few minutes there was a rapid improvement and visible subsidence of the facial œdema; the radial pulse, although quick and small, became palpable; the sensation of constriction departed. Vomiting, diarrhœa, and pyrexia followed with much malaise and some fever. In the evening there was still great irritation from the urticaria, but the case gave no further anxiety. It was later discovered that this patient had been given diphtheria antitoxin in childhood and that she had a bad rash. She has since shown herself liable to primula rashes.

It should again be noted that this patient received her second dose of serum while under an anæsthetic. A few years ago I had under my care a very anæmic patient, who had twice displayed violent and alarming immediate anaphylactic reactions following blood-transfusion, but whose response to a further transfusion, purposely given under anæsthesia, passed without anxiety.

On the experience of the three cases described the circulatory phenomena of anaphylaxis may be held to include pallor, tachycardia, initial coldness of the surface and extremities, and pulselessness due to a profound and sustained fall in blood pressure. In ordinary serum sickness a pulse-rate of 120 per minute is common. From the same cases we may also conclude that vomiting, purging, and diffuse pain are the outstanding abdominal symptoms of the anaphylactic state in man. Asthma, urticaria, "angio-neurotic" œdema, pyrexia, and multiple arthritis are among the other recorded symptoms.

DISTURBANCES ARISING WITHOUT APPARENT CAUSE

Let us now see how far these manifestations find a parallel (*a*) in acute and anxious disturbances arising spontaneously, or (more correctly) without apparent cause, and (*b*) in certain chronic or recurring disorders of less dramatic character.

CASE 4. *Abdominal Allergic Attacks; severe type.*—A married woman, aged 64, was brought to me by Mr. Hastings Gilford on Dec. 30th, 1931. Except for malaria many years previously her life had been healthy. *Her daughter suffered from asthma.* A year previously she had had an unexplained attack of malaise and sickness while abroad. In November, 1930, she had had a sudden severe attack of epigastric pain and cholecystitis was suspected. In January, 1931, she had an attack of quite a different kind, with violent generalised abdominal pain, vomiting, diarrhœa, and much shock. The vomitus was slightly streaked with blood. A succession of similar attacks followed at two to four weeks' interval. There were as many as four attacks within one period of a fortnight. An extreme degree of shock-like collapse was evident both to the patient and others around her. The acute phase was generally over within twelve hours. The X ray appearances of the gall-bladder were normal. She felt perfectly well between the attacks. A Chinese spiritualist, who affected to be able to see what was happening in the stomach, told her that she did not digest eggs! Most of the attacks had started at 2 A.M. *In one of the attacks her lips became tremendously swollen with angio-neurotic œdema.* In most of them her tongue was raw and red and her lips tended to peel afterwards. I could find no signs of organic disease.

CASE 5. *Abdominal Allergic Attacks; severe type.*—A medical man, aged 54, consulted me for the attacks to be described below. He had had malaria and pneumonia in childhood. *One brother had bad hay-fever.* Since childhood he had been liable to repeated abdominal attacks for which he had consulted many physicians. His longest free period had been nine months, his shortest ten days. The attacks generally started abruptly after premonitory lassitude. Fasting was a predisposing factor. In the attacks he had very severe generalised abdominal pain, starting under the rib margins, and of crescendo type. Nausea sometimes preceded, sometimes succeeded the onset of pain. Vomiting followed, and if it came early the attack passed more quickly. He was unable to eat or drink during the attacks, which would last from twenty-four to forty-eight hours. Throughout the attack he looked extremely pale and ill, and the pulse-rate rose to 120. He had a slight inguinal hernia, and during the attack "the sac seemed to fill with fluid," which he could press back into the abdomen. The abdomen was slightly swollen and it hurt him to take a deep breath. He had given up pork and bacon because one attack followed a pork pie, and mushrooms and fish because his skin had shown a slight reaction to these, but without benefit. In one attack a surgeon was called to see if he had appendicitis. Between the attacks he felt perfectly well. He had had *hay-fever* for thirty years, and for twelve years at intervals he had been subject to *angio-neurotic œdema* of his hand, arm, and perineum, and on five occasions of the palate and uvula, for which he had entered a nursing-home, fearing that tracheotomy might become necessary. Excepting for a right inguinal hernia and a myotonic right pupil, first noticed thirty years previously, there were no signs of any organic disease.

In both of these cases we find gastro-intestinal and circulatory phenomena closely comparable with those shown by the patients with anaphylaxis, and including shock, pallor, tachycardia, vomiting, diarrhœa, and abdominal pain. In addition we have, as confirmatory evidence, simultaneous or associated angio-neurotic œdema in both cases, hay-fever in one, and a solitary relative with an allergic disorder in both cases.

Before reviewing the less dramatic but more frequent allergic dyspepsias (in which circulatory manifestations are lacking or inconspicuous) there are further points in connexion with the vaso-motor phenomena of anaphylaxis and allergy which will bear consideration. Together with the objective pulse and blood-pressure disturbances of acute anaphylaxis from serum there may be associated the "sense of impending death" which, in conjunction with striking vaso-motor symptoms, is so pronounced a feature of vaso-vagal attacks (Gowers' syndrome). Vaso-vagal attacks chiefly affect patients who are, at the same time, physically unfit and in a state of anxiety. There is also, however, an occasional association between vaso-vagal attacks and migraine, asthma, epilepsy, spastic colon, and angio-neurotic œdema. All in fact proclaim an inborn hypersensitiveness which may be expressed in one or more of these several ways. It is rare in any of these to discover a specific sensitiveness as a basis for the vaso-vagal episodes, but an occasional case may develop symptoms in the first instance in response to a specific cause.

CASE 6. *Vaso-vagal Attacks following a Second Dose of Serum.*—A young man, aged 21 (a patient of Dr. A. W. Walters), whose feeding in infancy had caused much trouble and who had suffered from "mucous disease" until the age of seven, was thereafter fairly healthy until the age of eighteen. He then sustained a concussion and fractured a leg in a motor-cycle accident, and was given tetanus antitoxin. At the age of twenty-one he was involved in another motor-cycle accident, was again concussed, and fractured a small bone in his left hand, and was again given antitoxin. After this he was very unfit with urticaria and pyrexia, and developed attacks in which he was suddenly seized with a feeling of impending death and uncomfortable sensations about his heart. These attacks would last from half to one hour. When he sought to change his position things seemed to "black out" and he felt "wobbly" at the knees. He was terribly scared by these attacks, notwithstanding that he knew little of physical fear, was a keen rider to hounds, a member of the Auxiliary Air Force, and, as his history suggests, a none too cautious motor-cyclist.

The attacks continued for a time after the phase of serum-sickness. His father had experienced similar attacks at the age of twenty-seven but had outgrown them. I have no notes as to his appearance during these attacks but the subjective phenomena were those of Gowers' syndrome, of which the usual objective manifestations are pallor, coldness, and striking pulse and blood-pressure fluctuations. Had he experienced a solitary attack with urticaria immediately after the serum we should have accepted it as typical of anaphylaxis. It is reasonable to argue that the succession of attacks in this instance was initiated by a second dose of serum. The infantile and family histories suggest the conjunction with the therapeutic "experiment" of an appropriate "constitution."

ALLERGIC DYSPEPSIAS

It is not uncommon to meet persons who are aware of a food-idiosyncrasy. Shell-fish and eggs, especially duck's eggs, are well-known offenders and may give rise to gastric disturbance and erythematous or urticarial rashes. More rarely chocolate or coffee is blamed. Idiosyncrasies for drugs, not excluding those in common use like morphine (which may cause vomiting and collapse), are well recognised. The victims of these idiosyncrasies, however, although (like the horse-asthmatic) they exemplify a specific sensitiveness, usually have the sense to avoid what is poisonous to them and are rather less likely to consult us for recurring allergic disturbances than those whose sensitiveness lacks discoverable specificity. Of this latter group, I have selected a few examples from my files. The case histories illustrate some of the types of gastric and colonic disturbance which may be encountered and my reasons for regarding them as allergic.

CASE 7.—A medical man, aged 59, developed indigestion at a time of great strain. A suspicion of duodenal ulcer was entertained but not confirmed. At the same time he developed angio-neurotic œdema affecting the lips and eyelids particularly, and developing usually on waking in the morning. When he went on a holiday he lost both the dyspepsia and the angio-neurotic œdema. Later, with an access of work and worry, the symptoms recurred and the scrotum and penis also became affected by the œdema. At this time he did not lose the symptoms on a holiday. *His father had hay-fever. Two sisters and two brothers had asthma. One sister had chronic urticaria. His daughter was asthmatic.* His dyspeptic symptoms developed between two and three hours after food, and he sometimes had hunger-pain in the night. He was sleeping badly and was very tired when I saw him.

I found no signs of organic disease, and prescribed a third partner, medinal at bedtime, and an early retirement from practice.

He wrote to me eight months later as follows: "You will be interested to hear that since I have had better nights my digestive apparatus has been quite a different thing, and I have had no signs of the giant urticaria which troubled me last winter." Now, two years later, he has retired from practice and remains perfectly well.

Non-specific treatment, as with asthma, may sometimes play a useful part in "unconditioning" allergic symptoms.

CASE 8.—A young woman, aged 32, was brought to me by Dr. C. Boyson on account of a series of attacks of abdominal pain in the course of the descending colon, lasting perhaps twenty minutes. Six weeks and two years previously she had had bad attacks of pain in which she was "doubled up." For over ten years she had been worried by indefinite abdominal pains, and both the gall-bladder and the appendix had come under suspicion. At times she had feelings of extreme emptiness. She was of nervous type. She believed that influenza could precipitate an abdominal attack, and that worries and smoking aggravated. The gall-bladder was radiologically normal. There was indefinite tenderness in the right iliac fossa. In childhood and later she had been troubled with *eczema*, and throughout adult life by *hay-fever* and a spasmodic rhinorrhœa which was induced by proximity to horses. One brother was *asthmatic* and her father was a "*sneezer*." Later she was seen in an attack of cholecystitis with slight icterus and local tenderness over the gall-bladder.

CASE 9.—A retired mining engineer, aged 70 (referred by Dr. D. R. Pike), had suffered from heart-burn for many years with aggravation latterly. He was chiefly troubled between 3 and 6 A.M., when he was wakened by œsophatical burning and spasm, choking and hiccups, and would expectorate much watery fluid. A diagnosis of duodenal ulcer had been made by one physician, although there was no radiological confirmation. He was intolerant of salt meat and Vermouth, and knew his evening cigar "did him no good." His mother and maternal uncles had *asthma*. He himself showed a well-marked factitious *urticaria*.

CASE 10.—A married woman, aged 37, a patient of Dr. F. G. France, gave a long history of abdominal pain, had seen many physicians, and been fully investigated in a London hospital, without result or benefit. Seven years previously she had had a hysterectomy for menorrhagia and dysmenorrhœa. Her complaint was of a dull, aching, linear pain in the course of the descending colon, with aggravation by worry, exertion, and after defæcation, features characteristic of the "spastic colon." The stools were rather loose, and she had a feeling that the bowel was never empty. Apart from a myotonic left pupil there was no evidence of organic disease. She also suffered from *urticaria* and *hay-fever*, and her mother had suffered from *urticaria*.

CASE 11.—A married woman, aged 38, with three young children, was brought to see me by Dr. R. W. Todd, for recurring abdominal crises characterised by severe abdominal pain, profuse vomiting, even water being rejected, a temperature not exceeding 99°, and a quick pulse. There was general tenderness in the attacks with "semi-rigidity," but no distension. Appendicitis had been queried. In one attack the pain was chiefly epigastric; in another right-sided. Morphine had been given on one occasion. The attacks passed over in two or three days. After her last pregnancy a year previously the bowels had been slightly loose. One attack had followed shell-fish. She had also had slight attacks of *angio-neurotic œdema* affecting the lip and, following the last abdominal seizure, some "large raised bumps" on the back of the neck. She had always been liable to "acidity" and skin troubles. In her most recent attack there was headache. On several occasions she had experienced extremely severe attacks of *rectal spasm* lasting twenty minutes. Her first baby suffered from *universal eczema.* Apart from slight deep tenderness in the right iliac fossa there was no evidence of disease.

One of the chief difficulties in cases of this type is the differentiation from appendicitis. It is also to be remembered that appendicular infection or a gall-bladder infection may (as I have more than once been led to believe) act as the "sensitiser" in a patient with allergic tendencies. Diagnostic finality in cases of this kind may only be attained by a "follow up" over a period of years. The association of cutaneous or other allergic phenomena with abdominal attacks can never of itself exclude a more organic basis for such attacks.

CASE 12.—A married woman, aged 59, highly strung and fond of good living (seen with Dr. C. H. Atkinson), had shown unusually severe reactions to the extraction of teeth and also to vaccines prepared from them as a treatment for rheumatism. Over a period of two or three years she had several extremely severe abdominal attacks, starting with a girdle-like pain of colicky character, which at times "doubled her up" and necessitated morphine. With some of them she experienced headache. A year prior to my being called to see her she had been troubled by a very obstinate *urticaria*, which eventually departed after calcium injections. On April 12th, 1934, she felt "off colour," nervy and irritable, and then had one of these attacks with passage of pale stools, a temperature of 101·4, and a pulse-rate of 100. This attack, like the others, passed off "in a day or two." Possible precipitating causes had been shell-fish, smoked salmon and cream. She was intolerant of eggs and chocolate. As a child she had had bronchial troubles. Her doctor had seen her with spasmodic pain in the descending colon. I saw her on April 13th, and could find no signs of organic disease, and was of the opinion that her pains were colonic and, perhaps, an expression of allergy. On June 5th, 1934, she had a very bad attack of upper abdominal pain without vomiting, temperature 99°. There was some tenderness in the right iliac fossa. She was operated on that night for appendicitis (retro-cæcal) with localised peritonitis. After her wound had healed she experienced further trouble with obscure temperatures and abdominal pains.

Summary

Cases of "spontaneous" sensitisation or allergy have been compared with cases of "experimental" sensitisation or anaphylaxis. There is a close parallelism between the symptomatologies, subjective and objective, of serum-anaphylaxis and certain rare and alarming seizures occurring without apparent cause. These seizures are characterised by simultaneous gastro-intestinal and circulatory

symptoms, together with cutaneous manifestations or an associated history of these. They affect persons with individual and familial liabilities to asthma, hay-fever, and urticaria. In other persons showing similar liabilities we also discover a tendency to chronic or recurring disorders of stomach and bowel.

Generalised abdominal pain, vomiting, and diarrhœa, on the one hand, and pallor, tachycardia, and other shock-like manifestations on the other, are the features of the more severe and acute disorder. Recurring pain, of less intense type, in the gullet, stomach, and bowel, sometimes simulating organic disease, and looseness of the bowels are the main features of the more chronic dyspepsias.

There is little to distinguish the circulatory phenomena and subjective sensations of some vaso-vagal attacks (Gower's syndrome) from those of anaphylactic shock, and cases of Gower's syndrome may create, at the time of the attack, an equivalent degree of alarm. A case of Gower's syndrome following a second inoculation of tetanus antitoxin is described.

Referring to my notes of 19 cases filed under the heading of angio-neurotic œdema, I find, in addition to Case 7 two examples of associated dyspeptic disturbance and two of associated vaso-vagal attacks. A similar inquiry by cross-reference into my much larger asthmatic series would necessitate a more laborious inquiry, but the association of asthma with digestive and other allergic disorders is well recognised. With relapsing and evanescent disturbances such as those under review we depend, of necessity, for advances in our knowledge more upon detailed clinical observations and case histories than upon any other method of approach. The therapeutics of the individual case are also better served by close clinical scrutiny and adjustments based thereon than by allegiance to a particular method.

Conclusions

No abdominal or circulatory disturbance should be labelled as "allergic" unless two or preferably more of the following postulates are fulfilled :—

(1) The symptoms should bear close comparison with those observed in human anaphylaxis or serum-sickness.

(2) There should be a history of idiosyncrasy in respect of some food, beverage, tobacco, drug, or other extraneous substance.

(3) There should be observed, either in conjunction or alternating with the abdominal or circulatory episodes, other accepted allergic phenomena such as asthma, hay-fever, urticaria, or angio-neurotic œdema.

(4) There should be a family history of these disorders.

(5) The disturbances should show some such intermittency or periodicity as obtains with other allergic disorders.

(6) Every care should have been taken to exclude organic disease.

To these A. F. Hurst[2] would add the occurrence of eosinophilia and a favourable response to the therapeutic administration of adrenaline during attacks. My cases have all been seen in the course of consultative work, and I have had few opportunities of putting these additional tests to the proof.

BIOCHEMICAL BASIS OF THYROID FUNCTION *

By C. R. Harington, M.A., Ph.D., F.R.S.

PROFESSOR OF PATHOLOGICAL CHEMISTRY IN THE UNIVERSITY OF LONDON AT UNIVERSITY COLLEGE HOSPITAL MEDICAL SCHOOL

II

In my first lecture I indicated the way in which different lines of research have contributed to the solution of the problems of the normal function of the thyroid, of the chemical nature of the specific constituent of its secretion, and finally of the ætiology of simple goitre, and I attempted to show that the main facts were explicable on a simple biochemical basis.

I wish now to consider the biochemistry of the thyroid itself in more detail, in order to try to arrive at some conclusion regarding the nature of the actual secretion of the gland, and finally to discuss briefly some points in connexion with the biochemistry of Graves's disease which constitutes the outstanding unsolved question of the pathology of the thyroid.

Iodine Compounds of the Thyroid

In the first place the question arises whether the only use to which the thyroid puts iodine is the synthesis of thyroxine or whether other organic iodine compounds also occur in the gland. It will be remembered that under the best conditions the amount of thyroxine which can actually be isolated represents only a small proportion of the iodine present in the original material. Having regard to the great chemical stability of thyroxine it is difficult to suppose that the smallness of the yield is due to destruction during the process of isolation, more especially since only a small proportion of the total iodine appears in the inorganic form. There is therefore a strong suggestion that organic iodine compounds other than thyroxine exist in the thyroid, and if we study the matter more closely we find that such is indeed the case.

After the preliminary hydrolysis of thyroid gland with dilute baryta which constitutes the first step in the isolation of thyroxine we find that the iodine may be divided sharply into two approximately equal fractions. Acidification of the alkaline solution after hydrolysis produces a precipitate; in this precipitate is contained the whole of the thyroxine of the original material, and in accordance with this the precipitate also contains the whole of the physiological activity. The filtrate however contains about half the total iodine, nearly all of which remains in organic combination. Concentration of this acid-soluble organic iodine fraction followed by more vigorous hydrolysis and subsequent purification by recognised methods leads to the isolation of a pure iodine-containing compound which turns out in fact to be 3 : 5-diiodotyrosine. Furthermore, a careful quantitative study of the isolation of thyroxine and diiodotyrosine indicates that these two compounds between them account for the whole of the iodine of the thyroid (Harington and Randall 1929[1]).

The proof of the occurrence of diiodotyrosine in the thyroid evidently provides strong support for the hypothesis of the biological origin of thyroxine which was discussed in the previous lecture. At the same time the fact that separation of the iodine into acid-soluble and acid-insoluble fractions by mild hydrolysis is accompanied by concentration of the physiological activity in the latter seems at first sight to indicate that diiodotyrosine makes no direct contribution to the active secretion. Facts are now available, however, which cast doubt on the correctness of this assumption.

Relation of Thyroxine to Total Physiological Activity of the Thyroid

Although there is no known physiological effect of the thyroid which cannot be qualitatively reproduced by thyroxine it is quite impossible to equate the physiological activity of a given sample of thyroid with that of the thyroxine which can be isolated from it or even with that of the maximum amount of thyroxine which it can contain on the basis of the acid-insoluble iodine. The physiological comparison of whole thyroid gland with thyroxine is admittedly difficult and inaccurate, since thyroid gland can only be administered by mouth while thyroxine is only fully effective when given by injection; the preparation of a degradation product of thyroglobulin which I shall shortly describe however has made it possible to surmount this difficulty in an indirect manner, and it is now perfectly clear that a loss of physiological activity is indeed involved in the process of isolation of thyroxine.

Such a loss of activity might be explained in various ways. As has already been pointed out, the great stability of thyroxine makes it unlikely that it has undergone any change in its molecular constitution during the process of isolation, so that it is unnecessary to assume that thyroxine represents an artificial transformation product of a more active precursor until all more probable explanations fail. One change will however undoubtedly have occurred during the isolation of thyroxine—namely, racemisation due to the alkaline hydrolysis employed. Since physiological activity is often profoundly influenced by stereochemical configuration the effect of this alteration on the physiological properties of thyroxine must first be considered. A decision on this point can be reached by the pharmacological comparison of the artificially prepared optically active forms of thyroxine, as a result of which it appears that *l*-thyroxine (which will subsequently be shown to be the naturally occurring form) is only some three times as active as *d*-thyroxine (Gaddum 1929–30). The most recently published results indicate indeed that the difference in activity between the two forms is even less than this, so that it is obvious that racemisation will not help us to explain the deficit of activity of thyroxine compared with that of the thyroid gland from which it is derived.

A line of investigation which has thrown some light on this problem is one which was designed primarily with the purpose of isolating optically active thyroxine.

It has already been mentioned that the earlier workers on the chemistry of the thyroid were unsuccessful in their attempts to isolate the active principle by enzymic hydrolysis of the gland. A renewed attack on the problem (Harington and Salter, 1930) showed however that under properly chosen conditions a far-reaching degradation of thyroglobulin could be effected by the aid of proteolytic enzymes without the simultaneous extensive liberation of iodine from its organic combination which had frustrated previous attempts. The main factor in the success which was finally attained was the use of large amounts of highly active preparations of the various enzymes, so that the time to which the material was exposed to the conditions of digestion was reduced to a minimum. The working up of the hydrolysis products was further facilitated by the fact that throughout the course of digestion the fraction containing thyroxine retained a characteristic isoelectric point, about pH 5, at which its solubility was low and at which therefore it could be separated by precipitation from the other products of hydrolysis.

By intensive digestion of thyroglobulin with pepsin, separation of the products insoluble at pH 5, and redigestion of these with trypsin, a degradation product could be obtained which contained about 15 per cent. of iodine. Subjection of this material to a succession of chemical fractionations which need not be discussed in detail but which involve no drastic treatment led eventually to a product from which a small amount of thyroxine could be separated. This thyroxine was lævorotatory, as had been anticipated from the fact already mentioned that *l*-thyroxine is the more active isomeride.

From our present point of view however the main interest of these experiments lies in the properties of the digestion product of thyroglobulin which was left in the mother-liquors from the final isolation of thyroxine. This material contained about 50 per cent. of iodine, all of which could be shown to be present in thyroxine; moreover, analyses of the iodine and nitrogen contents showed that all the thyroxine which was present must be in peptide combination with other amino-acids, which were estimated to be three or four in number.

This relatively simple thyroxine-containing material derived from natural sources has a range of solubility much greater than that of thyroxine itself, and is readily absorbed when given by mouth; on the other hand, owing to its reasonably low molecular weight, it can also be administered intravenously with safety. It can therefore be compared on the one hand with whole thyroid gland by the oral route and on the other with free thyroxine by the intravenous route. We have thus for the first time the possibility of obtaining an effective comparison between the real physiological activities of thyroxine and whole thyroid gland.

The results of comparison of the thyroxine peptide with free thyroxine show, as is to be expected, practical identity of action when the compounds are injected and an enormous difference of activity in favour of the peptide when both are given by mouth, the doses in all cases being calculated on the basis of equivalence in iodine.

When the peptide was compared with whole thyroid gland, both being administered orally, it appeared at first as if the peptide were definitely more active than the equivalent amount of thyroid, and I was myself persuaded at one time that this experiment explained the discrepancy under discussion. For if these results had been correct they would have meant that the activity of thyroxine in the peptide was enhanced as compared with that of the free compound by virtue of the very fact that it was in peptide combination. Even though the apparently superior activity of the peptide was not quantitatively great enough to account for the whole of the discrepancy, the general conception of the enhancement of the activity of thyroxine by combination with other amino-acids seemed adequate to account for the facts, for there was no reason to suppose that the properties of this particular peptide, obtained as it was by artificial digestion of thyroglobulin, represented the highest degree to which such enhancement of activity could attain in the actual secretion of the gland.

Work which has appeared since, however, has forced me to the conclusion that this hypothesis, at least in the simple form outlined above, can no longer be maintained. The extensive and careful investigations of Salter have shown conclusively that the peptide has identical activities when given by mouth and by injection, and that, iodine for iodine, a dose of peptide by mouth is equivalent to one of thyroxine intravenously. On the other hand, the peptide and whole thyroid gland have practically identical physiological activities when given by mouth, the tests being made by the most accurate available method—namely, by the effects on the basal metabolic rate in human myxœdema (Salter, Lerman, and Means, 1933; Means, Lerman, and Salter, 1933). Since thyroid gland, as has already been shown, does not usually contain more than half its iodine in the form of thyroxine, it is evident that we are still left with a very serious discrepancy to explain.

Possible Nature of the Actual Secretion of the Thyroid

I am unable at the present time to offer an explanation of the difficulty which can claim any experimental support. I am, however, unwilling to accept the facile explanation of the loss of activity involved in the isolation of thyroxine which is based on the assumption that total destruction of an independent active principle is caused by the methods of isolation employed. Not only is there complete lack of positive evidence in favour of such an assumption, but all the knowledge which we possess of the chemical features responsible for the type of physiological activity exhibited by thyroxine indicates the intrinsic unlikelihood of the existence of a second unstable active principle. The matter seems to me sufficiently important to justify a little theoretical consideration, and I should like briefly to outline a hypothesis which seems to me to be adequate to cover the facts as at present known.

Until recently the generally accepted method of chemical assay of thyroid gland for therapeutic purposes consisted in estimation of the total iodine content, on the assumption that all of this iodine was involved in the active principle. When it was shown by the work which I have described that in actual fact only a part, and a somewhat variable part at that, of the total iodine represented thyroxine, the remainder being present in the form of the physiologically inactive diiodotyrosine, it seemed reasonable to base the chemical assay of thyroid gland on its content of thyroxine-iodine rather than of total iodine. A method based on this principle, for which I regret to say I am myself largely responsible (Harington and Randall, 1929[2]), has been adopted in the new British Pharmacopœia; in this the preparation of thyroid is standardised to contain a certain amount of iodine which is insoluble at pH 5 after preliminary alkaline hydrolysis, and which may therefore be taken to represent thyroxine. Now it was shown by Gaddum and Hetherington (1931) that the physiological activities of various preparations of thyroid did not in fact run strictly parallel with their thyroxine-iodine contents; furthermore, carefully conducted recent work, particularly that of Salter already referred to, seems to show that the activity of any given preparation of thyroid is determined after all by its total iodine content, and that therefore the original method of assay by total iodine content was fundamentally correct.

If this is indeed the case, and if we accept the experimental results which I have described and which show (*a*) that the whole of the iodine of the thyroid can be accounted for between thyroxine and diiodotyrosine, and (*b*) that after preliminary mild hydrolysis the whole of the physiological activity is concentrated in the thyroxine-containing fraction, we are forced to the conclusion that this mild hydrolysis has effected some change as a result of which proportionality has ceased to exist between total iodine and physiological activity; we must further assume that, in so far as the whole gland is concerned, the diiodotyrosine fraction must contribute to the activity, although when separated this fraction is entirely inactive.

I can conceive of only one explanation which will fit these facts—namely, that the molecule of the complete active secretion of the thyroid contains both thyroxine and diiodotyrosine and that some linkage between these two is ruptured during the hydrolysis which is a necessary initial stage in the isolation of thyroxine. As a result of such a rupture it would not be surprising to find residual physiological activity confined to that fraction which contains the more highly specific and characteristic constituent—namely, thyroxine.

I do not suggest that the linkage between thyroxine and diiodotyrosine is direct; indeed I am fairly certain that it is not so, for, having with some difficulty synthesised both thyroxyldiiodotyrosine and diiodotyrosylthyroxine, I have been surprised and somewhat disappointed to find that both these peptides are less active than thyroxine itself. This negative result however does not mean anything, for it is possible and indeed likely that in the active secretion the iodine-containing amino-acids are united through an intermediate chain of ordinary amino-acids. Experiments bearing on this point are in progress in my laboratory at the present time and in the meanwhile the whole conception must remain entirely hypothetical. I feel, however, that it does afford a reasonable explanation of the two main difficulties with which we are still faced in connexion with the normal biochemistry of the thyroid—that is, the loss of activity involved in the isolation of thyroxine and the fact that the activity of the whole gland is proportional to the total iodine and not to the thyroxine which it contains.

If we may for the moment assume the truth of the idea which I have advanced we may now form a connected picture of the normal series of events in the thyroid gland. It is well known that the thyroid possesses a very strong affinity for iodine and that any of this element which finds its way into the blood stream is rapidly concentrated in the gland. It may be supposed that the iodine which reaches the thyroid is first introduced into the molecule of tyrosine to form 3:5-diiodotyrosine. The latter will then fulfil a dual rôle; part of it will be converted into thyroxine by a process the nature of which I have indicated and another part will be linked with the thyroxine so formed together with other amino acids to form the true active principle of the gland. This active principle will then in turn be built up into the molecule of thyroglobulin and stored as such in the form of the colloid until it is released in accordance with the metabolic demands of the body.

Constitutional Factors in Relation to Activity of Thyroxine and Allied Compounds

Before finally leaving the question of the chemistry of thyroxine it may be of interest to discuss [illegible] the chemical features of the thyroxine [illegible] which appear to be of significance for [illegible] physiological activity, particularly [illegible] siderations have a bearing on [illegible] Graves's disease which have to be [illegible]

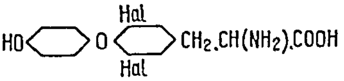
The most obvious chemical [illegible]

molecule of thyroxine are the presence of the *o*-diiodophenolic group and of the phenylether linkage. Neither of these groupings alone however is sufficient to confer thyroxine-like activity upon a compound as is shown by the total absence of such activity from diiodotyrosine and α-amino-β-di (3 : 5-diiodo-4-hydroxyphenyl) propionic acid on the one hand and from thyronine on the other. The aminopropionic acid side-chain seems to be necessary, since such compounds as thyroxamine (decarboxylated thyroxine) are devoid of activity. The full complement of iodine is not necessary for the qualitative development of the characteristic physiological activity, since 3 : 5-diiodothyronine will produce a rise in the basal metabolic rate equivalent to that produced by about 1/40 of its weight of thyroxine (Gaddum, 1929–30). 3 : 5-Diiodothyronine has indeed considerable therapeutic possibilities; it is a much more soluble compound than thyroxine and is readily absorbed when given by mouth; in appropriate doses it produces a marked rise in metabolic rate without any tendency to cause disturbances such as sometimes accompany medication with thyroxine or thyroid gland, and it possesses the obvious advantage over thyroid gland that the dose can be controlled with absolute precision (Anderson, Lyon, and Harington, 1933).

Strangely enough iodine itself may be replaced by another halogen without total loss of physiological activity; 3 : 5 : 3′ : 5′-tetrabromothyronine, the bromine analogue of thyroxine, exhibits the characteristic physiological activity of the latter, although naturally in a very much lower degree. This suggests the possibility of an entertaining experiment; it would be interesting to see whether an animal with a hyperplastic thyroid resulting from elimination of iodine from the diet would respond to administration of bromine by involution of the gland with accompanying synthesis of tetrabromothyronine in place of thyroxine.

It will be apparent that in this as in so many other fields the attempt to relate chemical constitution with physiological activity does not meet with any great measure of success; all that can be said with certainty is that obligatory requirements for the development of thyroid-like activity are the presence of the thyronine nucleus and the substitution of this nucleus with halogen atoms at least in the 3 : 5-positions (Fig. 4). It is however to be noted that no change in the molecule of thyroxine has done anything but diminish physiological activity and that no such change has caused the development of any toxic properties.

FIG. 4



Biochemical Basis of Graves's Disease

I now come to the last and most difficult subject with which I have to deal—namely, the biochemistry of Graves's disease. I approach this with diffidence, for it is disappointing to realise how little the great advances which have been made in the study of the biochemistry of the normal thyroid and of simple goitre help towards an understanding or towards treatment of the most serious disorder to which the gland is subject.

The information to be gained from the morphological or chemical examination of the thyroid itself in Graves's disease is not very great, since with equal severity of symptoms great variations both in the gross size and in the histology of the gland may be found. In general however, unless the patient has been treated with iodine, the amount of colloid is diminished and such colloid as is present is abnormal in appearance and consistency. There is always more or less hyperplasia of the glandular epithelium. As we should expect from these appearances the iodine content of the gland is low.

The morphological appearance of the thyroid in Graves's disease is similar to that of a thyroid which has undergone hyperplasia in a normal animal as the result of restriction of iodine and the Graves's disease thyroid responds to administration of iodine in a similar manner—namely, by involution with storage of colloid. The fundamental difference which distinguishes the thyroid in Graves's disease from that in the normal organism is the greatly increased rate at which the former pours out its secretion. Administration of iodine to an animal with a hyperplastic thyroid resulting from iodine deficiency causes at most a slight and temporary increase in the rate of secretion of the gland; in Graves's disease on the other hand the physical changes of involution and colloid storage which occur in response to iodine administration are accompanied by a period of restricted secretion followed by subsequent release of the active principle at as great a rate as ever, although the appearance of the gland may be relatively normal. It seems then that the thyroid in Graves's disease is suffering, as Kocher (1910) expressed it, from a "diarrhœa" in which the gland retains its natural avidity for iodine—and even its capacity for storing iodine if sufficient be supplied—but is forced, as soon as the iodine has been converted into the physiologically active secretion, to pour the latter out. The cause of the "diarrhœa" may be an intrinsic abnormality of the thyroid itself, or it may be the action of an extrinsic stimulus; since the gland still possesses its storage capacity for iodine the latter alternative seems the more likely.

Iodine Therapy in Graves's Disease

Since Graves's disease is always associated with more or less enlargement of the thyroid and since other forms of goitre had been successfully treated by administration of iodine it is not surprising that attempts were made from time to time to treat Graves's disease in the same manner. The results of such attempts were however very variable; they were occasionally reported as favourable but more often as disastrous, and the general attitude until recent years was that expressed by Trousseau (1867–73) in describing a favourable result which he had himself obtained by the accidental prescription of iodine; in general he regarded iodine as a most dangerous drug to use in Graves's disease. This point of view became profoundly modified as the result of the work of Plummer at the Mayo Clinic (Plummer and Boothby, 1924; Boothby, 1924) some ten to fifteen years ago, which indicated that striking, if temporary, improvement could be effected in patients suffering from severe Graves's disease by the administration of large amounts of iodine, and that such treatment was of great value at least as a pre-operative measure.

Now the revival of iodine therapy in Graves's disease introduced by Plummer was based upon certain theoretical considerations which had first been raised by Möbius (1896) 25 years earlier. Möbius, whilst convinced that Graves's disease was the result of abnormal activity of the thyroid, inclined to the view that this abnormal activity consisted in the production of an abnormal toxic secretion rather than in simple hyperactivity; in other words, dysthyroidism would be a better description of the condition than hyperthyroidism. Plummer defined this hypothesis more narrowly by making the additional assumption that the toxic secretion in Graves's disease was a modification of the normal secretion deficient in iodine; on this idea was based the hope that administration of excess of iodine might convert a toxic dysthyroidism into a less dangerous straightforward hyperthyroidism.

The undoubted success which can often be obtained in the treatment of Graves's disease by Plummer's method appears at first sight to afford confirmation of his theory, but a more detailed examination of the evidence leads to a different conclusion. In order to establish the theoretical basis of Plummer's hypothesis it is necessary to demonstrate a clear difference between the symptoms arising from Graves's disease ("dysthyroidism") and those arising from other forms of hyperthyroidism ("adenomatous goitre" or "toxic adenoma") and this demonstration is not easy to make. It is perfectly clear that the major symptoms of Graves's disease—namely, increased basal metabolic rate, loss of weight, tachycardia, nervous disturbances—could quite well be accounted for by simple hyperthyroidism and have in fact been known to be associated with excessive administration of thyroid ever since the introduction of replacement therapy in myxœdema; moreover, these symptoms occur also in "adenomatous goitre with hyperthyroidism." There is left the symptom of exophthalmos which is usually characteristic of human Graves's disease, but this scarcely seems a sufficient basis for the qualitative differentiation of Graves's disease from other forms of hyperthyroidism with which it has so much in common. Moreover, it appears from recent work that even this symptom can be produced experimentally in animals by a method which involves stimulation of the thyroid to continued hyperactivity.

The symptoms arising from adenomatous goitre are not influenced or are only influenced to a relatively small extent by iodine medication, and this fact has also been adduced in support of the qualitative differentiation of Graves's disease from other forms of hyperthyroidism; the argument is fallacious however, since it is well known from the work of Marine (1913) that thyroid adenomata, which are of unknown origin but must be regarded as functioning thyroid tissue, differ quantitatively from ordinary thyroid tissue in being much less responsive to variations in exogenous iodine supply; it cannot therefore be expected that a hyperplastic thyroid containing these growths should respond to iodine in the same way as a hyperplastic thyroid free from adenomata such as is found in Graves's disease.

It appears to me therefore that there is little support either on the ground of symptomatology or on that of therapeutic observations for the assumption of a qualitative difference between Graves's disease and straightforward hyperthyroidism. Moreover, the dysthyroidism theory is open to serious positive criticisms. The beneficial effect of iodine therapy in Graves's disease is limited in duration, usually to about three weeks; if Plummer's modification of the theory were correct there should be no such limitation.

It should be possible to demonstrate experimentally the presence of a toxic principle in the glands removed from patients suffering from Graves's disease; all attempts to do so have failed. Indeed, as is to be expected, the more severe the disease the greater is the degree of glandular hyperplasia and the less iodine is contained in the thyroid; in such cases the gland material is practically devoid of physiological activity.

Finally, as has been pointed out, no derivative of the normal active principle containing less than the full complement of iodine has been found to approximate quantitatively in activity to thyroxine or to possess any toxic properties whatever.

In view of the lack of positive support of the dysthyroidism theory of Graves's disease, and in consideration also of the serious criticisms which can be advanced against it, I feel some confidence therefore in dismissing the hypothesis as an unnecessary complication and in holding to the simpler assumption that all the symptoms of the disease may be regarded as manifestations of the presence in the body of excess of the normal active principle of the thyroid; furthermore, it seems to me to be fairly certain that the over-production of the active principle is due to the action of an extrinsic factor upon the thyroid. If these assumptions are to be justified however some explanation must be given (*a*) of the temporarily beneficial effect of iodine therapy, and (*b*) of the nature of the extrinsic factor which causes the thyroid "diarrhœa." Neither of these questions can be fully answered at the present time, but in both cases it is possible to make suggestions which may be worth consideration.

First of all, in connexion with iodine therapy, the most significant fact seems to be that the beneficial effect, although often dramatic, is only temporary; as a general rule the maximum improvement as indicated by diminution of the basal metabolic rate is obtained after about three weeks; thereafter the good effect gradually wears off and there is little evidence that any permanent benefit can be conferred by continued iodine medication alone. Moreover, intermittent iodine medication in Graves's disease is a definitely dangerous procedure, since there is evidence that resumption of iodine administration after an intermission may produce an acute exacerbation of symptoms. It is a matter of indifference in what form the iodine is given apart from the risk of producing iodism by the administration of large doses of inorganic iodine, a risk which may easily be avoided by giving the iodine in the form of diiodotyrosine. (This method has the theoretical advantage that the iodine is supplied in the form in which it is required by the thyroid and the practical advantage that much smaller doses of iodine are required.) In whatever form iodine is given it has precisely the same effect upon the gland—namely, that which is characteristic of the action of iodine on a thyroid which has undergone hyperplasia from any cause whatever. There is involution of the glandular hyperplasia and storage of colloid and these processes take place with great rapidity. It is this rapidity of effect which suggests a possible explanation of the favourable action of iodine in the early stages of its administration; the rapid swelling and hardening of the gland owing to colloid storage under iodine medication are often physically evident, and it has been suggested by Marine that it is this acute distension of the gland which causes an inhibition of outpouring of secretion, since the pressure set up prevents the secretion from obtaining access to the lymphatics in the ordinary way. Such a mechanical conception certainly accounts for the temporary nature of the effect, for as soon as the structural elements of the gland have been able to adjust themselves to the altered conditions the secretion will no longer be mechanically retained and the rate at which it is poured out will gradually increase until it reaches the level determined by the stimulus which is working on the gland—a state of affairs which is in entire accordance with the observed facts.

Whether this be the correct explanation of the action of iodine in Graves's disease or not it is of the greatest importance, in my opinion, that the temporary nature of the effect should be fully realised. Moreover, not only is the effect temporary but it cannot be elicited to the same extent a second time even after a long interval. The real justification of iodine therapy in Graves's disease is its value as pre-operative treatment; the attempt to use it for prolonged and unaided medical treatment is not only, according to all the evidence, foredoomed to failure, but means the loss of an opportunity to put the patient into the most favourable condition for operation. Surgical treatment of Graves's disease has indeed no basis in reason, and is at best a palliative measure; in the present state of ignorance however it seems to be the most effective way of dealing with the situation, and it appears to me unfortunate that iodine therapy should be sometimes regarded as a rival of surgical treatment when it should in reality be its ally.

Possible Extrinsic Factor in Graves's Disease

It remains finally to consider what may be the nature of the extrinsic stimulus producing the "diarrhœa" of the thyroid gland which we have concluded to be the essential feature of Graves's disease. From the welter of unrelated and ill-digested observations on the relations of the thyroid with other endocrine organs two facts stand out clearly. The first is the inhibitory effect upon the thyroid of the suprarenal cortex and the second the stimulating effect upon the thyroid of the anterior pituitary.

The first of these effects manifests itself normally in the increase of heat-production of a child which coincides with the involution of the suprarenal cortex occurring a few days after birth (Lewis and Pappenheimer, 1916; Marine, 1922); it has also been shown experimentally by Marine and Baumann (1921) and others that severe injury to the suprarenal cortex will cause an increase of heat production so long as the thyroid is intact, but not after thyroidectomy. The relationship of these facts to Graves's disease however, if indeed such a relationship exists, has not been established. No lesion of the suprarenal cortex in Graves's disease has been observed nor have the few good results at first claimed by Marine in the treatment of patients with Graves's disease with suprarenal cortical extracts been confirmed. The suprarenal cortex-thyroid relationship does not therefore take us far in the direction in which we wish to go.

It is possible that the anterior pituitary-thyroid relationship is more significant. Whilst it has long been recognised in a rather vague manner that the thyroid and pituitary are related, it is only in the last few years that it has been shown clearly that among the numerous hormones elaborated by the anterior pituitary is one which has the specific property of stimulating the thyroid to hypertrophy (Loeb and Bassett, 1929; Closs, Loeb, and Mackay, 1932; Krogh, Lindberg, and Okkels, 1932). The changes induced in the thyroid by the action of this thyrotropic hormone are precisely similar on the one hand to those produced in a normal animal by restriction of iodine intake and on the other to those which occur in Graves's disease. That is to say there is hypertrophy of the gland due to hyperplasia of the epithelium accompanied by loss of colloid and of iodine. Moreover, these changes are accompanied by physiological manifestations of hyperthyroidism; indeed, there is no symptom associated with hyperthyroidism which cannot be produced by administration of thyrotropic hormone and it even appears that with the aid of this substance the experimental production of exophthalmos in animals has become possible (Schockaert, 1932; Loeb and Friedman, 1932).

Since the thyrotropic hormone is able to elicit these effects in presence of a supply of exogenous iodine which is normally adequate, it is evidently causing a "thyroid diarrhœa" analogous to that which has been postulated as the essential feature of Graves's disease; it is tempting therefore to suppose that the anterior pituitary plays a rôle in the disease as it is seen in human beings. Here again, however, objective evidence in favour of such a supposition is entirely lacking, and in the present state of knowledge I believe it to be unjustifiable to make an assumption of this sort. One of the most remarkable discoveries in connexion with the thyrotropic hormone is that due to Collip (Anderson and Collip, 1934)—namely, the possibility of producing an antiserum by prolonged treatment of an animal with thyrotropic hormone which will antagonise the effects of the latter. It seems scarcely conceivable that this antiserum owes its effect to the production of a true antibody in the immunological sense, since the occurrence of such an antibody would be a negation of the power of the thyrotropic hormone to continue its action in the normal organism. It is, on the other hand, just possible that the antiserum contains an antagonistic principle elicited from another source—e.g., the suprarenal cortex—and that its production is thus a manifestation of a balance between two organs of internal secretion having opposing effects on the thyroid.

This somewhat complicated hypothesis is entirely without experimental support; I put it forward only to indicate my opinion that although the thyrotropic hormone has been shown to be a potential causative agent of Graves's disease, it is extremely unlikely that anything so simple as the over-production of this hormone can account for the condition. It appears to me unquestionable that the problem of the ætiology of Graves's disease involves complexities which are as yet unsuspected; it is permissible to hope however that these complexities may ultimately be unravelled by physiological and biochemical investigations such as those now being conducted in connexion with the thyrotropic hormone, and that finally it may be possible to discuss the biochemical basis of Graves's disease with as much confidence as we can now discuss the biochemical basis of normal thyroid function.

PHOSPHATASE IN FRACTURES

By E. H. Botterell, M.D. Manitoba
FELLOW IN SURGERY, UNIVERSITY OF TORONTO; AND
E. J. King, Ph.D. Toronto
FORMERLY ASSISTANT PROFESSOR OF MEDICAL RESEARCH AT THE UNIVERSITY *

(From the Department of Surgery and the Department of Medical Research, University of Toronto, Canada)

This investigation was undertaken in order to evaluate the part played by the bone enzyme, phosphatase, in the repair of fractures. Robison[1] has shown that the phosphatase mechanism plays an important part in the calcification of bone, and that in the ossification of the skeleton the enzyme is found only with the appearance of hypertrophic cartilage cells and osteoblasts. The presence of the enzyme results in the liberation of free phosphate, due to the hydrolysis of the organically bound phosphoric acid of the plasma. There is a consequent local increase in the concentration of phosphate ion which results in a super-saturation with respect to calcium phosphate of the fluid bathing the matrix of the bone. A second mechanism, not fully understood, appears to favour the deposition of the bone salt from the supersaturated solution.

The problem was approached with the object of finding (1) if the phosphatase content of the bone and callus in the region of a fracture is higher than that of the corresponding normal bone; (2) if the phosphatase content is raised, can it be related to the increase in the number of osteoblasts and hypertrophied cartilage cells in the callus; (3) if there is any increase in the phosphatase of the blood-serum, at the same time as repair of the fracture is occurring
1931 (McKeown and Ostergren)[2]; (4) if the introduction of a potent preparation of phosphatase into the fractured area would cause any change in the calcification of the callus or in the histological picture.

A series of experiments was carried out using uniform transverse fractures in the radii of rabbits. Serum phosphatase and bone phosphatase estimations were made at appropriate intervals.

Experimental Methods

Technique of producing experimental fractures.—The rabbit was operated on under ether anæsthesia. An incision was made over the middle of the right radius where it is subcutaneous. The muscles were separated from the shaft of the bone. By means of an Albee motor saw the radius was sawn through, leaving the ulna as a natural splint. The skin was closed with silk. Aseptic precautions were used. This technique was followed uniformly throughout on one or both sides, and with or without the introduction of phosphatase, as the experiment required.

Technique of preparing bone for estimation of phosphatase and histological examination.—The rabbits were killed by a blow on the back of the head. By careful dissection the bones of the fore-legs were denuded of soft tissues. The fractured radius was cut across so that a segment was obtained which extended half an inch proximal and half an inch distal to the site of fracture. A corresponding segment was prepared from the normal radius when required. These segments were cut longitudinally with a fine fret-saw. One half was used for the estimation of phosphatase; the other half was fixed in formalin, decalcified, and stained for histological study.

Phosphatase estimation.—The half segment of radius was carefully weighed and ground. It was then extracted with fifty times its weight of water for 48 hours. A few drops of chloroform were added as a preservative. The turbid extract was filtered through a plug of cotton-wool and the phosphatase content of the filtrate determined by the phenyl phosphate method of King and Armstrong.[3]

Phenylphosphate is a more suitable substrate than the glycerophosphate previously used for the determination of phosphatase; it is hydrolysed much more rapidly and the liberated phenol is more conveniently determined than the phosphate (three times as much phenol as phosphorus by weight is hydrolysed). The method is easily and quickly carried out and is suitable for the clinical laboratory. Duplicate determinations can be completed in 1 hour.

Duplicate samples of 0·5 c.cm. of bone extract or of serum are added to 10 c.cm. M/200 phenylphosphate in M/20 veronal (1·09 g. di-sodium phenylphosphate and 10·3 g. sodium veronal in 1 litre). The tests are maintained at 37° C. for 30 minutes. The enzyme action is stopped and the proteins precipitated by the addition of 4·5 c.cm. of a 1 : 3 dilution of Folin-Ciocalteu's[4] phosphotungstic-phosphomolybdic acid phenol reagent. Duplicate controls are made in the same way, but the enzyme action is stopped immediately by the addition of the phenol reagent. The mixtures are filtered. 10 c.cm. filtrate are treated with 2·5 c.cm. 20 per cent. Na_2CO_3 to bring up the blue colour due to free phenol. Colorimetric comparison is made with an 0·1 mg. phenol standard. The increase in free phenol is taken as a measure of the amount of enzyme present. The results are expressed in terms of the mg. phenol which would be hydrolysed by 1 g. of bone (i.e., by 50 c.cm. of extract) or by 100 c.cm. of serum. Each mg. of phenol liberated is considered the equivalent of 1 "unit" of phosphatase.

Technique of preparation of phosphatase powder.—The phosphatase preparation which was introduced into the site of fracture was prepared according to the method of Martland and Robison.[5] The phosphatase was finally suspended in absolute alcohol. This was removed in a vacuum desiccator at room temperature. The dry powder was tested for phosphatase activity and sterility.

The Experiments

Group 1.—In order to study the phosphatase content of bone during the process of repair the right radius was fractured in 23 fully grown rabbits. The rabbits were killed at intervals up to 73 days, and the phosphatase content of the fractured area of the right radius was compared with the phosphatase content of the corresponding area of the normal left radius. In two rabbits the specimens were discarded on account of the formation of an abscess at the site of operation. In each of the 21 remaining animals the phosphatase content of the fractured radius was higher than that of the control radius (see Chart 1). This increase was seen as early as

the fourth day after fracture. From the results of this series of animals it would appear that there is an increase of phosphatase at the site of fracture for at least 50 days.

Group 2.—Transverse fractures were produced in both the right and left radii of six rabbits. These animals were killed over a period of 22 days. A definite rise occurred in the phosphatase content of both radii. An approximate similarity was found in the increase of phosphatase at both sites of fracture in the same animal.

TABLE I

Bone Phosphatase in Fractures (both Radii Fractured)

Days.	Left radius.	Right radius.
1	0·6	0·8
5	0·8	1·0
8	10·3	7·4
13	9·0	7·0
15	15·4	15·7
22	19·2	17·1

Group 3.—Transverse fractures were produced in both radii of 27 rabbits. About 5 mg. of phosphatase, representing approximately 3 units, were introduced into the fracture of the right radius at the time of operation. This amount was about four times as much as that usually found in a segment of normal radius. The powder used at each operation was found to be sterile, both by smear and culture, but in four cases sterile abscesses developed.

As is seen in Chart 2, there was a marked rise in the phosphatase content of both fractured radii. The quantities of phosphatase found did not differ materially in the treated and untreated fractures. It would appear that either the phosphatase was removed rapidly from the site of its introduction (by being carried away in the blood stream or by being destroyed in situ), or its presence may have militated against the production of phosphatase by the normal mechanisms. This latter possibility could well be due to the presence of considerable amounts of denatured protein in the phosphatase preparation, although the material used had been purified to the greatest possible extent and was of as high enzymic potency as any previously prepared.

SERUM PHOSPHATASE

The phosphatase of the serum was estimated at intervals in a number of rabbits in all three groups.

Group 1.—The level of the serum phosphatase was investigated following the operation in 12 of the 23 rabbits. Estimations were made at weekly intervals up to 10 weeks post-operatively, on a decreasing number of animals. Neither any consistent increases nor, in fact, any significant changes were demonstrated. One animal showed abnormally high readings throughout, and a second animal had a terminal rise in the seventh, eighth, and ninth weeks.

In *Group 2* the serum phosphatase remained normal in the 6 rabbits throughout the experiment.

In *Group 3* the serum phosphatase was done at weekly intervals for four weeks. All estimations were normal and further estimations were not done.

Thus it would appear that there is no significant rise in the level of serum phosphatase in rabbits following fractures of one or both radii; nor was any rise demonstrated following the introduction of phosphatase at the site of fracture.

HISTOLOGICAL EXAMINATION

Of the segment of bone removed from the site of fracture as described above, half was used for the estimation of phosphatase and half was studied histologically. In the preparation of the bone for phosphatase estimations it was necessary to remove the soft tissues. There occurred, therefore, the loss of variable amounts of periosteum and some osteoid tissue. This fact rendered difficult the histological interpretation of some of the sections. We are indebted to Dr. A. W. Ham, of the department of anatomy, for his careful study of the sections, which was made independent of any knowledge of the changes in phosphatase activity or of the duration of the fracture. Twelve fractures with the introduction of phosphatase, and 34 uncomplicated fractures, were examined histologically.

In the majority of the sections examined a small amount of foreign material was present. This was due to bone dust formed as a result of using a motor saw. There were practically no foreign body reactions.

Hypertrophic cartilage cells were seen in sections of bone removed soon after fracture. These cells persisted and formed a prominent feature in the histological picture, along with osteoblastic activity and matrix formation, until the sixth week when they diminished. Osteoblastic activity and the formation of bone matrix persisted for a further three or four weeks. The phosphatase content of the bone remained at its previous high level for some three weeks after the diminution in hypertrophic cartilage cells was evident. The phosphatase found at this stage may be taken to represent production due to the continued osteoblastic activity.

In every instance where osteoblastic activity and matrix production were high, there was a high degree of phosphatase activity in the other half of the segment of bone. In no specimen was a high phosphatase content recorded in the absence of hypertrophic cartilage cells, or osteoblastic activity and the formation of a matrix.

In the group of rabbits where phosphatase was introduced into the fracture, three died and three were killed during the ten days following operation. No histological sections were available from the segments of bone removed from these six animals.

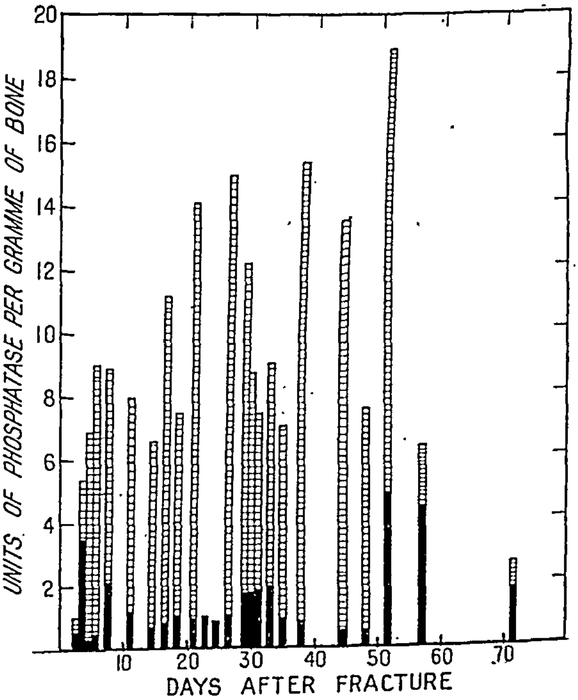

FIG. 1.—Phosphatase content of fractured and of control radii. Hatched column represents amount of enzyme in fractured segments; blackened column, amount in control segments.

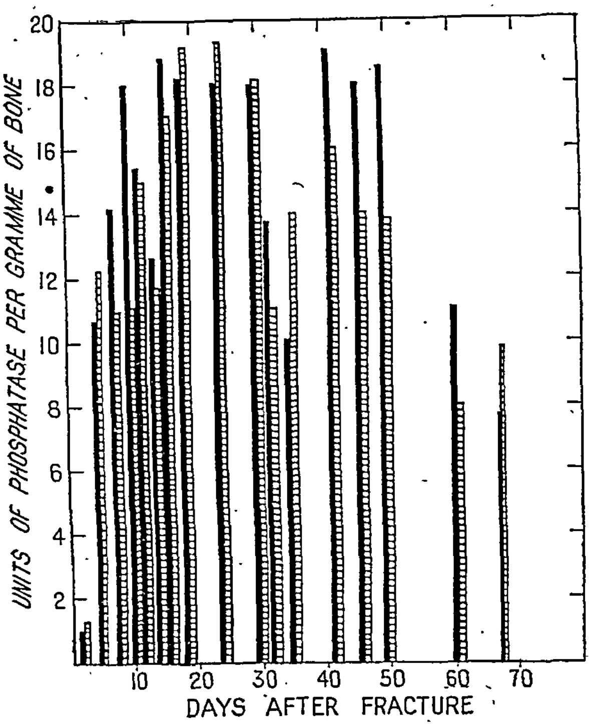

FIG. 2.—Phosphatase content of fractured radii. Hatched column, fracture of right radius with the introduction of phosphatase: blackened column, fracture of left radius (without introduction of phosphatase).

The gross appearance, which included œdema and congestion of soft tissues and the presence of some white pasty material at the site of fracture, suggested a non-suppurative inflammatory process. Sections were taken from the fractured radii of 12 rabbits killed from 10 to 67 days after operation. Examination failed to reveal any difference in the gross or histological evidence of repair, as seen in the fractures into which phosphatase had been introduced and the control fractures on the opposite legs. No evidence of the presence of the phosphatase powder could be found. No foreign body reactions were apparent.

Serum and Bone Phosphatase in Human Cases

At the same time as the animal experiments were under way, the level of serum phosphatase was investigated in a group of patients admitted to the fracture service of the Toronto General Hospital. Estimations of the phosphatase content of bone from the region of the fracture were carried out whenever possible. In two cases a sufficient amount of the hæmatoma at the site of fracture was obtained to allow of determination of the phosphatase content. The results of the serum phosphatase readings in this group of patients have been classified according to age, and according to whether bony union developed. A separate group was established for pathological fractures. Serum phosphatase is normally higher in persons under 21 years of age. The average range is from 15–20 units per 100 c.cm. of blood for the ages from 12 to 20 years. In adults the average range is from 5–10 units. These facts must be borne in mind in considering the level of serum phosphatase readings in this group of patients.

Closed fractures with bony union in patients from 15 to 21 years of age.—In a group of five patients four showed a series of normal serum phosphatase readings. One case only showed evidence of a rise in serum phosphatase. This patient (a boy of 18 years) suffered a fracture separation of the lower epiphysis of the femur. The serum phosphatase shortly after admission was 14·3 units. It rose to 32 units in three weeks and then gradually fell. As at this age the growth of the femur is not complete and the epiphysis has not yet united, the phosphatase content of the bone at this site would normally be high. 30 c.cm. of hæmatoma fluid aspirated at the time of injury contained the large amount of phosphatase of 30 units per 100 c.cm.

Fractures in patients over 21 years of age which resulted in bony union.—The group comprised 21 patients. Five of the cases required operative measures for purposes of reduction and fixation. Serum phosphatase determinations were carried out up to 12 weeks after the time of the fracture. In two cases there was evidence of a slight increase in serum phosphatase. The highest reading obtained was 17·2 units, so that the increase is of doubtful significance. A portion of the organising hæmatoma from between the fragments of a fractured olecranon, two days after the injury, showed 0·51 unit per gramme (about 50 units per 100 c.cm.).

Fractures resulting in non-union.—One case of non-union was studied in a patient below 21 years of age. Five months of immobilisation of the compound fracture of the humerus in this boy of 15 had failed to result in union. The serum phosphatase was about 25 units prior to operation and ranged from 25–30 units for the six weeks following a successful bone graft. In three cases of fracture of the neck of the femur in adults which resulted in non-union the serum phosphatase remained within normal limits.

OBLITERATIVE ARTERIAL DISEASE TREATED WITH MUSCLE EXTRACT

By M. Schwartzman, M.B.

HONORARY FIRST [illegible], LONDON JEWISH HOSPITAL

In 1928 J. Schwarzmann (Odessa) suggested the use of skeletal muscle extract¹ in the treatment of angina pectoris, especially in cases where angiospasm is likely to be a prominent factor. At about the same time Vaquez, Giroux, Kisthinios, and Gley (Paris) recommended the injection of an insulin-free pancreatic extract (Angioxyl); Frey and Kraut (Düsseldorf) introduced a circulatory substance (Kallikrein) which is obtained from the urine, but is also probably of pancreatic origin; while Zuelzer (Berlin) put forward a liver extract (Eutonon) which he later modified so as to contain both liver and muscle. After a few years of trial muscle extract seems to have established itself in practice more

At the end of January, 1935 (four years [illegible] ceased), he reported that he was free from p [illegible] in the legs, even on walking two or three [illegible] becomes bluish on exposure, but it is [illegible] On examination I found blanching with [illegible] but return of colour was prompt on bot [illegible] (40° above horizontal).

Case 2.—A man, aged 62, when seen in [illegible] gave a history of intermittent claudicat [illegible] His walking distance had gradually decreas [illegible] and for the last three months he had had [illegible] his left foot which became persistently blu [illegible] patches had appeared on three left toes. [illegible] feet, particularly the left, much swollen, [illegible] deeply cyanosed. The skin on three toe [illegible] down: the big toe was black with a green pa [illegible] the broken surface, and there were similar endeavour to obey. If ordered to strike a given person, that person will be relentlessly pursued until the blow has been given. No physical hardship or discomfort is allowed to stand in the way; to plunge into freezing water in the depth of winter or to bathe in boiling water offers no deterrent, and so commonly is this the case that at times mischievous youths under the influence of liquor, have, through their thoughtless pranks, caused considerable commotion and trouble by orders given in this way to an innocent cataleptic patient.

In some patients the negative aspect of these three forms of reaction appear equally clearly. Instead of repeating what is said to them they answer with a direct opposite; instead of imitating movements they make one, the significance of which is exactly the reverse; instead of obeying suggestions they act in a directly contrary manner. Thus, the reply to "one" will be "two"; to "Sapporo," "Kushiro"; to "bikki" (frog), "kaimachike" (skeleton); to "man," "kuruma" (a Japanese woman). When shown a closed fist the patient will extend her open hand and vice versa; if the observer bends, the patient will stand more erect; if ordered to approach she will retire; if bidden to withdraw she will hasten nearer; if beckoned she will look uninterestedly away, while if the observer manifests no interest she will endeavour to attract his attention.

Our attempt to photograph an "imu" patient was frustrated by the patient's objection until the photographer in disgust said "Very well then, I won't photograph you," when she hurriedly changed her attitude and begged to be filmed.

DISCUSSION

This condition appears in a race of a low cultural standard, and it is interesting to note that similar maladies are to be found amongst the natives of Malay, the Yakuts of Siberia, and the American Indians, other races whose cultural level is recognised as being lower than that of the average. The primitive spiritual life of these peoples, with their countless superstitions, legends, and traditions, and their high degree of suggestibility, are the chief causes that favours the appearance of this malady amongst the Ainu. Further, the symptoms themselves are such as may be expected in those following primitive lives still closely patterned upon the instinctive behaviour of lower animals. The echolalia and the echopraxia both in their positive and in their negative forms are strongly reminiscent of the behaviour often observed in normal children, for children will not only repeat instinctively what they hear and copy what they observe, but will also often with equal innocence and lack of malice attempt to assert themselves in withholding the answer they know to be desired, in refusing to comply with requests and in a general perversity of behaviour which appears exactly similar to the negativism of the "imu-futchi." The other less particular and less deliberately directed forms of behaviour can be equally well paralleled in the instinctive behaviour of lower animals. The excesses of violence appear like the futile and undirected flight of a bird that has wandered into the unfamiliar surroundings of a room and is attempting blindly and instinctively to escape. The cataleptic inertness can be equally well paralleled by another naturally occurring form of self-defence, that observed for example in a spider or in a woodlouse which, when suddenly disturbed, will become instantly inactive, presumably for the natural purpose of feigning death or of passing unobserved.

Thus all the symptoms of the "imu-futchi" may be regarded as due to the operation of instinctive forms of self-defence or of instinctive forms of self-assertion which are to be commonly observed in lower forms of life, which play some part in the behaviour of our own children, and which are occasionally copied for our own purposes as when we assume a defensive immobility when threatened by some beast of prey. If this view is accepted with regard to the symptomatic *content* of the attacks, it must not be inferred that the *form* of the "imu" attack is that which is commonly observed in the hysterical symptomatology of races on a higher cultural level. "Imu" and hysteria have many points in common, but the regularity with which an attack can be provoked, the suddenness of the onset, and the transitory duration, all suggest that "imu" has more automatic qualities and is easier to arouse than are hysterical attacks. The echo-symptomatology, both of hysteria and of "imu," loses in time its direct connexion with mechanisms of self-defence and becomes a mere habitual reaction, the significant inference from such patients being not that their mental content or that their instinctive reactions are any different from those of normal persons, but that they are temperamentally or constitutionally less resistive to emotional strain and are therefore liable to outbursts of emotional decontrol when faced with certain stimuli which leave the normally balanced unaffected.

If we ask why it is that the malady should appear in this particular form among the Ainu peoples, the answer is to be found in a consideration of the spiritual and domestic characteristics of that race. Their spiritual life is peculiarly primitive and, as with all such races, their degree of suggestibility is high. In this race also the social status of women is very clearly defined; the woman is forced through habit and custom to be completely submissive to the man, and this suggests one reason why the attacks may be so largely confined to women past the middle age and why they may take this particular form. Two incidents which I witnessed may serve to illustrate the argument. An old Ainu woman was sent rolling down a bank of mud by a maudlin Ainu man. In spite of this insult she did not offer a single word of protest nor any act in self-defence; her daily training in habitual submission was too strong. In another community two "imu" patients who had been aroused to an attack fell upon the men surrounding them and showed their undisguised joy in having thrown one of these to the ground.

Thus, we may regard both hysteria and "imu" as being due to repressed resentment, the relief from which repression takes the form of paroxysmal outbursts in which instinctive forms of self-defence find violent expression or dominate the behaviour, and we may further suggest that the resentment which activates the "imu-futchi" patient is that occasioned by the subordinate and submissive place to which she is relegated by Ainu tradition.

GIFT TO WELSH HOSPITAL.—At the opening of the new radiological department and ward block at the Swansea Hospital on May 16th it was announced that Mr. D. W. Davies, of Ystalyfera, Glamorgan, had given the sum of £10,000 to the hospital. The gift has made it possible to open the new buildings free of debt.

BUCHANAN HOSPITAL, HASTINGS.—It has been arranged to proceed with the building of the new nurses' home which is badly needed. Over £4500 is already in hand for this purpose, but another £500 is still required.

"IMU"

A MALADY OF THE AINU*

BY DR. Y. UCHIMURA
PROFESSOR OF MEDICINE, THE UNIVERSITY OF HOKKAIDO

THOSE habits of mind and of behaviour, which are peculiar to a given people, and which are commonly referred to as racial characteristics, may show themselves not only in common features of everyday life, but in emotional or spiritual predispositions which are, as a rule, revealed only in those individuals of the race who are the victims of some mental disturbance which renders them liable to attacks of emotional decontrol. When such psychopathic individuals break down under an emotional strain, the symptoms which appear are the result of an interplay of intellectual and emotional reactions which do not differ essentially in kind from those which characterise the more stable members of the race, and therefore an accurate study and complete understanding of the mental ailments peculiar to a given race is only possible when one has already a knowledge of the faith, superstitions, customs, and other domestic peculiarities of the people in question. This relation is a reciprocal one, and it is often found not only that such knowledge enables us to interpret morbid symptoms, but that the symptoms themselves reveal or explain otherwise obscure native superstitions.

The malady to which the name "imu" is given is found among the Ainu where it is very frequently observed, although it has attracted little attention in the medical literature of other parts of the world. In 1901 Dr. Yasusaburo Kasaki published a detailed report on this subject. Although apparently less common now than in his time, the malady is still endemic and even in the smallest communities one or two susceptible patients can be found. It is almost entirely restricted to women who have passed middle age. From our own investigations we have gained the impression that those "imu" patients whom we have observed have been slightly above the average in intelligence and sometimes also in their standard of living: their level of instruction is not lower than the normal, and they are found at all levels of social standing.

Personal observations, confirmed by information derived from their neighbours, makes it clear that in between the attacks which characterise this malady the patients are free from any peculiarities of behaviour and they are in no way to be distinguished from other members of the community. The condition of "imu" makes the patient liable to attacks of psychomotor disorder precipitated by some emotional shock. The word "imu" may be translated as meaning "severe shock": the condition itself is referred to in native parlance as "imu-futchi" or "imu-bakko," each of these suffixes meaning "old woman." It is sometimes also referred to as "tokkoni-bakko," "tokkoni" being the native word for viper, a reptile the exhibition or mention of which frequently precipitates attacks and an abhorrence of which is deeply interwoven in local superstition. Of all these terms "imu-futchi" appears to be the most suitable.

The symptoms of an attack may be many and varied, the severity depending to some extent upon the degree of emotional disturbance associated with the precipitating stimulus. But this is not always so. In some patients the mention of anything at all that is emotionally disturbing, but particularly of the words "tokkoni" or "bikki" (Ainu: bikki = frog), will lead to a sudden outburst of violence in which a woman previously perfectly normal in behaviour will act as though trapped and terrified or confronted with some immediately vital peril; she will attack indiscriminately everything that enters her range of vision, seizing as weapons anything that lies to her hand, and throwing about sticks and stones in a violent but aimless manner. Such patients may be extremely dangerous to persons around if they can seize upon a knife or any weapon; also under the influence of this excitement they are capable of exerting an amount of muscular power which would never have been expected from one of their build and age. Thus, one old woman of 70 completely destroyed a toy snake which was shown to her, by her furious blow which she delivered with her cane. At times patients will attack onlookers and then fly in terror. From this description it will be seen that these outbursts of violence may be regarded as due to the unrestrained and undirected operation of a very primitive instinct for self-defence.

The attacks do not last for more than a few minutes and the patient very quickly returns to complete normality: some appear to have no recollection of their behaviour during the attacks, while others seem to be deeply ashamed of their conduct. With less severe emotional shocks, or in patients who are less easily aroused, the disturbance often takes another form. Thus if, for instance, in the course of an ordinary conversation with a patient one's friendly tone is suddenly discontinued and a word is uttered which is not pertinent to the subject under discussion, the patient may appear suddenly bemused and will continue for a time to echo everything that is said to her. "One," you say to her and "one" the patient echoes; "you fool," and "you fool" is the answer; "bow," and she returns "bow-wow." At times such a patient will echo remarks made not to her but to someone or to something else; thus, on one occasion, while trying to get a dog to bark before feeding him with a piece of cake, I prompted him by saying "bow-wow"; to my surprise the answer came not from the dog but from an "imu-futchi" who had been standing under the eaves of a dwelling some way away and who repeated "bow-wow, bow-wow!" The patient's echoing is independent of any significance the words may have for her, for words of a foreign language are repeated in the same way. Similarly, actions are copied; clapping the hands, raising the arms, and pushing the patient backwards all elicit similar acts on the part of the patient; a condition which may be similarly described as echopraxia as distinguished from echolalia.

When in this bemused condition patients are highly susceptible to suggestion; they no longer exercise independent control of their actions and are not really answerable for the consequences of these; they will carry out orders with the utmost precision and if placed in a given position will remain cataleptically in that exact posture until released by permission to do so. If ordered to dance, the quietest and most submissive of women will dance such steps as are recognised as being an essential prerogative of the men, and a woman of over 60 will dance as gaily and as lightly as a girl, not ceasing until she is so ordered and continuing until so fatigued that she is unable for some time further to stand. If bidden to do something not within the limits of her physical ability she will nevertheless valiantly certainty of sound union and full functional use within a reasonable period.

---

* Translated from the Japanese by Miss Amy Neichl.

A plaster-of-Paris slab made of several thicknesses of three-inch impregnated bandages is moulded to the volar aspect of forearm and hand after satisfactory reduction. Sponge rubber is then applied over the dorsum of the wrist. First a three-inch-square piece of half-inch thickness is placed directly on the skin and then over this, along the line of the joint, a strip one inch thick and one inch wide is applied. These are drawn down firmly by an encircling plaster-of-Paris bandage, applied over the pads in the form of a St. Andrew's cross, leaving thumb and fingers free. An annular band is also applied distal to the elbow to retain the upper part of the slab in position. Voluntary movement to the full range permitted by retentive apparatus is encouraged for fingers and thumb. At the end of three weeks the pressure pad has done its work and can be removed by splitting the side attachment of the St. Andrew's cross component. For a further three weeks the volar slab provides adequate and satisfactory splintage; it can be periodically removed for massage and gentle movement. I do not suggest that at the end of six weeks car-cranking can be safely undertaken; but the arm and wrist is strong enough for most light or medium work. An elastic adhesive bandage can with advantage be applied to give further support to the wrist at this stage.

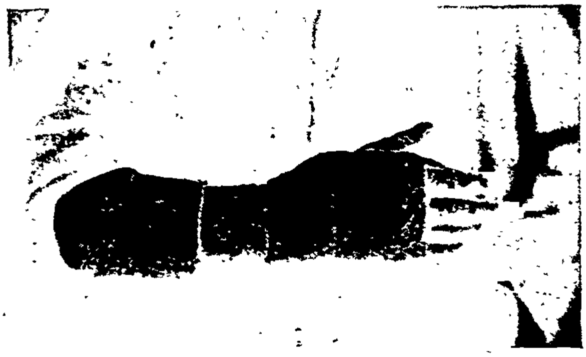

FIG. 2.—The splint applied.

Fig. 2, showing splintage as applied (with sponge rubber pad enclosed) gives probably a more definite and immediate idea of the method than any written account.

Bourne, Lincs.

MEDICAL SOCIETIES

ROYAL SOCIETY OF MEDICINE

SECTION OF MEDICINE

FOLLOWING the annual general meeting of this section on May 28th, Sir FARQUHAR BUZZARD, the president, being in the chair, several short communications were made, the first by Dr. C. C. UNGLEY on

Parenteral Liver Therapy

in pernicious anæmia and subacute combined degeneration. He showed two cinema films, one lent by Dr. W. P. Murphy of Boston dealing chiefly with the hæmopoietic effect of liver extract administered intramuscularly. This demonstrated the economic advantages of the parenteral route; the blood regeneration was more rapid than with liver extract given by the mouth. Simultaneous administration of iron hastened the rise of hæmoglobin concentration. A monthly injection of 3 c.cm. of liver extract (Lederle), derived from 100 grammes of liver, was usually sufficient to maintain the red blood-cell count at or above 5 millions per c.mm. In conjunction with re-educational exercises, the method gave good results in patients with subacute combined degeneration. Amongst other illustrations the film portrayed a patient, unable to stand or walk without help, whose gait three months later was almost normal.

The second film, taken in Newcastle-upon-Tyne, depicted the condition of patients with subacute combined degeneration before and during intensive parenteral liver therapy. Campolon and Pernæmon forte were given in amounts varying from 15 to 42 c.cm. a week. In most cases there was improvement in gait and in the symptoms and signs of neurological involvement. The change was sometimes striking, in that patients with severe ataxia and paraplegia recovered their ability to walk and even returned to their original employment. In one instance improvement followed the use of short-wave electrical pyrexia, parenteral liver therapy alone having ceased to be effective.

Dr. G. GREGORY KAYNE spoke of the use of

Sanocrysin in Pulmonary Tuberculosis

He said that although ten years had elapsed since Møllgaard's first publications on sanocrysin, wide differences of opinion still existed as regards indications, mode of application, and results obtained. His remarks in the present paper were based on observations made from personal contact with several continental workers. It was generally agreed that sanocrysin had no marked effect on tubercle bacilli in vitro. Møllgaard claimed at first that it had a direct bactericidal effect in the animal body, and advised the use of a serum prepared by immunising healthy animals, in the belief that it would neutralise the toxins presumably liberated by destruction of the bacilli and the cause of the severe reactions which followed. The appreciation that the metal itself might play a rôle in producing reactions, their diminished frequency with smaller doses, and the varying results obtained with the serum led to rejection of the theory of a direct bactericidal action. Alternatively it had been suggested that sanocrysin might act as an aid or stimulant to the natural tissue defences. O. Bang could not confirm Møllgaard's curative results in calves and maintained that the findings were due to using attenuated bacilli for infecting the animals and unreliable controls. Madsen and Mørch obtained positive results in rabbits, but later both they and K. A. Jensen were unsuccessful in repeating the findings. In England Lyle Cummins reported favourable results in rabbits, and Atkin concluded that sanocrysin exerted an inhibitory effect on tuberculous lesions apart from any bactericidal action it might have. Reviewing the guiding principles of sanocrysin therapy in the centres visited by him, Dr. Kayne first referred to the work of Secher, and pointed to the circumstances which prevented a just estimation of the part played by the sanocrysin in the reported results. Secher's indications were wide, and his initial dosage the highest administered at present, in the belief that "reaction greatly activates the cure"; yet his total dosage was low. His results were thus probably due to "shock therapy." Gravesen's use of sanocrysin was based on the early exudative lesion being the ideal indication, whether occurring by itself or in association with an older process. He found it a valuable aid in collapse-therapy and used moderate increasing dosage

CLINICAL AND LABORATORY NOTES

A CASE OF B. COLI MENINGITIS

By T. A. Ratcliffe, M.B. Camb.

LATE HOUSE PHYSICIAN, SHEFFIELD CHILDREN'S HOSPITAL

Meningitis due to *Bacillus coli* is uncommon. Findlay[1] states that of 789 consecutive cases of meningitis admitted to the Glasgow Royal Hospital for Sick Children between 1914 and 1929, only one was due to this organism. The condition was first described in 1895 by Schreer,[2] but only 42 cases had been reported by 1926, when the literature was reviewed by Neal.[3] Gibbens[4] in 1932 reported 3 more.

X. Y., a girl aged 6 weeks, was admitted to the Children's Hospital, Sheffield, on Feb. 1st, 1935, with a history of "convulsions at intervals for 12 days." Previous to this she had been quite well, and the onset had been sudden. There was nothing in the history to suggest birth injury, and she was a breast-fed baby. For the 12 days there had been several convulsions a day, during which "she went blue and twitched." Between the convulsions she lay still, but if her head were touched she screamed. She was constipated, and she had vomited several times. On examination the child was semi-comatose and the respirations were stertorous. The head was hydrocephalic, the sutures were all widely opened, and the fontanelle was bulging. There was marked head retraction and a positive Kernig's sign; pupils equal, but reacting sluggishly to light; abdominal reflexes absent; legs very spastic; knee-jerks much accentuated. The other bodily systems were normal.

A lumbar puncture was performed on the day of admission, and about 2 c.cm. of clear fluid was obtained (there was no increase of pressure), followed by a free flow of what appeared to be pure blood. The child's condition progressively became worse, and she continued to have several convulsions each day, the head becoming definitely more hydrocephalic. Up till Feb. 5th the temperature remained normal, but after this it rose gradually, being 100° on the 7th, 101° on the 12th, and 104° on the 13th. The pulse-rate rose from 150 to 170, and the respirations from 36 to 58. The child died on the evening of Feb. 13th.

A second lumbar puncture had been performed on Feb. 4th, with the same result as before. With so little fluid obtainable, only culture was attempted, and this gave a pure growth of the *Bacillus coli*. The mother's Wassermann reaction was negative, and radiography of the child's skull revealed no abnormality apart from the hydrocephalus. Post mortem the brain was found to be very large; the ventricles were distended with thick semi-mucoid greenish pus, the cortex being reduced to paper thickness in places. There was much pus at the base, and fairly dense adhesions between the medulla and the cerebellum. Films from the intracerebral pus showed very numerous Gram-negative organisms resembling *B. coli*. The other bodily systems showed no abnormality.

B. coli meningitis seems to be seen more often in children, especially infants, than in adults. Convulsions are usually a conspicuous feature, but the signs are frequently equivocal and do not always point so clearly to a meningitis as they did in this case. The actual diagnosis can, of course, only be made after lumbar puncture. Characteristically, the cerebro-spinal fluid is difficult to obtain. In one of Gibbens's cases aspiration was necessary, and in another no fluid could be obtained. The explanation of this appears to be the presence of much pus, and even adhesions, around the base of the brain, a state which was well marked in this case, and which Boyd[5] also describes. It is this, of course, which produces the hydrocephalus also. *B. coli* meningitis is usually considered to be a terminal event in a *B. coli* septicæmia, and some focus of infection is usually found elsewhere in the body, the middle ear being a very common site. No such focus, however, was found in this case, either clinically or post mortem, and careful questioning suggested that the onset was sudden without any prodromal symptoms. There was, moreover, no pyrexia until the latter half of the illness. Boyd[5] has described a case in which no primary focus of infection could be found. No case of recovery from *B. coli* meningitis appears to have been reported, and treatment is of no avail.

I am indebted to Dr. H. Leader, under whose care the case was, for permission to publish this report, and to Dr. H. E. Harding for details of the post-mortem examination.

CHAUFFEUR'S FRACTURE

By W. B. R. Monteith, M.A. Camb., F.R.C.S. Edin.

Unlike a Colles fracture, which may vary quite considerably within certain limits, chauffeur's fracture has stereotyped and distinguishing features. These are too well known to need description; the accompanying photographs (*Fig. 1*) show appearances that are typical. Joint involvement is noteworthy as the cause of the pain that accompanies this lesion—pain which is more than usually severe. Accordingly, like other fractures complicated by joint-involvement, it demands complete initial immobilisation. As with the fracture of the base of the first metacarpal that goes by the name of Bennett's fracture, there is an aggravating (and sometimes disappointing) tendency for the [illegible] fragment to become redisplaced after entirely [illegible] The following method seems to justify description as a means of securing painless immobilisation with

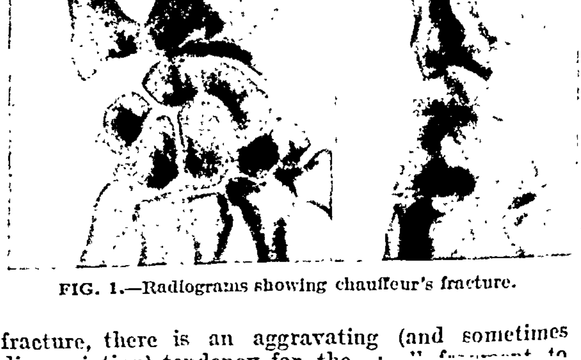

FIG. 1.—Radiograms showing chauffeur's fracture.

Of the 118 patients personally attended by Dr. Pickles, the charts relating to 23 in whom it was possible accurately to trace the chain of infection, strongly supported an incubation period of about a month, though there are, he thinks, two forms of this disease, one with an incubation period of only 2-5 days. His observations suggest that its infectivity is low and that the period of infectiousness is short. Careful observation of the alarming but transient symptoms of a disease up till then unknown in the district, enabled Dr. Pickles and his partner, the late Dr. Dean Dunbar, to identify it as epidemic myalgia or Bornholm disease. Dr. Pickles also brought forward observations in support of the belief that herpes zoster and chicken-pox are variants of the same disease. But while the Wensleydale villages are still comparatively isolated and remote, the centralisation of schools has afforded opportunities for the dissemination not only of knowledge but also of infectious disease. A zealous teacher, not realising she was suffering from influenza, in a single morning gave rise to 78 cases in an area up till then free from the disease. In an outbreak of Sonne dysentery, it was invariably the children attending school who first became ill in each of the families affected.

The PRESIDENT, Sir WILLIAM HAMER, Dr. S. MONCKTON COPEMAN, and others took part in the discussion. The work of Dr. Pickles reminded Dr. J. A. GLOVER of a cross between that of Hippocrates and of Gilbert White, and Dr. P. STOCKS spoke of the compound solution of antibodies which passes for normal serum in town-dwellers. Dr. E. W. GOODALL was not prepared to abate the orthodox latitude of incubation periods. Surgeon Captain S. F. DUDLEY agreed, but regarded the study of infection in a comparatively natural population as of great value. Prof. M. GREENWOOD underlined the "fundamental" importance of such work which he considered comparable to that of William Budd and entitled to the widest publicity. The study of the natural history of epidemic disease was of first-class importance; more and more recorded observations of this kind were needed. The communities under Dr. Pickles's observation being less artificial than either mouse herds or ships' companies, deserved the closest study.

CHELSEA CLINICAL SOCIETY

AT a meeting of this society held on May 21st at the Rembrandt Hotel, with the president, Dr. CHARLES SUNDELL, in the chair, a discussion on

Sexual Problems in General Practice

was opened by Prof. MILLAIS CULPIN. The first sex problem in practice, he said, was the practitioner himself. Just as there were practitioners temperamentally incapable of evaluating psychoneurotic symptoms and who therefore never heard them, so there were practitioners who, by their attitude, warned off any attempt to seek their advice on sex difficulties. Any doctor who was unable to ask a question about details of sex life without lowering his voice had better leave the whole subject alone. A practitioner who said he had never met a case of sexual perversion confessed to a personal inhibition. Some difficulties were purely artificial. The problem of sex education for the young only existed in the mind of the adult. There was no problem, therefore, if parents were free of taboo and answered questions with as little emotion as they would give answers about growing potatoes. Once a child had accepted the taboo, a barrier was built up, and this must be recognised by the practitioner, who could rarely penetrate it. To find out what a boy of 12 knew about sex was generally impossible, and the attempt might be recommended to the authors of little books on "What a boy of 12 should know." Adolescent girls might be asked: "Do you want to know?" and if the answer was "No," it must be accepted. If it was "Yes," the frankest possible explanation should be given, not omitting the emotional urge. To present the sexual act as a physiological process for the purpose of impregnation would make emotional difficulties worse. The adult who declared that he had known nothing of sex till the age of 18 was not uncommon. The state was probably a physiological dissociation, and was often associated with a rich unconscious phantasy life.

Masturbation was coming to be regarded as a normal phase of sex development, which made the handling of patients easier. Solemn warnings and attempts at restraint produced lasting harm. Impotence had such varied causes that every case was a separate problem. A conscious or unconscious attitude to sex as something shameful and almost sinful offered an obvious point of attack, and a discussion of the patient's upbringing might reveal twisted views. In impotence, however, the œdipus situation often called for full psycho-analysis; it was indicated by the patient's placing women in the two classes of angels and inferior beings. The worst problem was offered by the healthy woman married to an impotent man who regarded his impotence as a virtue. The practitioner in such a case should never approach the husband on the subject, nor should he tell a woman that her nervous symptoms were due to her husband's impotence. That they are her way of reacting to the situation may be true and an understanding of that view may help her. Frigidity was often part of a psychoneurotic condition and might react to the same treatment. Vaginismus was hysterical.

Homosexuality was often felt as inevitable and unquestionable, but the subject might be unscrupulous or filled with horror at himself. The second type could be helped by discussion, for he was a very isolated individual. Women rarely sought treatment for homosexuality and rarely felt distress at it. The question occasionally arose whether homosexuals ought to be school-teachers. If the condition was recognised and could be frankly discussed by the person concerned, there was less danger. Psychotherapy was not a magic wand, and was useless unless the homosexual wanted to be put on the other track. Generally, when it came to the point, he did not.

DISCUSSION

Dr. JOSEPH GEOGHEGAN divided sex problems into two classes: departures from ordinary sexual behaviour, such as impotence, homosexuality, and frigidity; and departures from ordinary social behaviour involving problems of everyday life. The doctor got to know of these things through being more than a mere doctor. A very sound rule was to consider that one would not oneself want advice. The difficulty should be surveyed with common sense. Advice should not be given. Everybody was abnormal and apt to project his or her difficulties and moral standards. Principles were for oneself; charity for others. The best thing that the general practitioner could do was to be kind, and to send the patient to somebody who understood the subject better.

Dr. TRAVERS SMITH stressed the importance of not telling a woman that the sudden appearance of a neurosis was due to the impotence of her husband.

with short intervals, attempting to avoid reactions. After referring to Faber, Permin, and Würtzen in Copenhagen, and pointing out that in Norway and Sweden sanocrysin had not been used in recent years, Dr. Kayne dealt with Sayé's work in Barcelona. The latter's results were more telling owing to the very inadequate sanatorium accommodation and the low economic level in Spain. Sayé, too, believed the early exudative lesion to be the ideal indication, but advocated the use of the salt in other types of cases. Beginning with very small, he rose to large doses, being guided in that and as regards intervals by the type of case and the reactions, which he grouped as (1) focal, (2) those due to metallic intolerance, and (3) those due to metallic saturation. He had also used gold in ambulant patients, as is also extensively done in the clinics of the late Léon Bernard in Paris.

Summarising, Dr. Kayne concluded that the clear indications for sanocrysin were: (1) recent exudative lesions, unless cavitation was already present; (2) similar lesions associated with old-standing disease, either contralaterally or homolaterally when detected by serial skiagrams; and (3) as an ambulatory treatment in certain cases detected during the routine examination of apparently healthy individuals. Severe constitutional symptoms should be regarded as a relative contra-indication to sanocrysin. He did not think its use justified as a placebo. The best dosage appeared to be a progressive increase from small doses, the intervals to be based on the principles laid down by Gravesen and Sayé.

Dr. BURGESS BARNETT, speaking of the

Hæmostatic Use of Snake Venom

outlined the results of clinical trials which solutions of this venom have now received at St. Bartholomew's Hospital and elsewhere. This work was a sequel to the preliminary report by Dr. R. G. Macfarlane and himself in THE LANCET of 1934, ii., 935, in which it was concluded that the venom of the Indian snake, Russell's viper, contained a powerful blood-coagulant which it was suggested would prove of value as a hæmostatic both in normal and hæmophilic hæmorrhage. The venom, he said, behaved as though it contained activated prothrombin and it was employed as a local application to increase the prothrombin content of the blood as the latter was shed. Used in this way, in a dilution of 1 : 10,000, it was without toxic effect; the venom-formed clot of a hæmophilic was as tough and elastic as that of normal subjects, and it was formed just as rapidly. Cases in which it it had been employed fell into three groups: hæmophilic subjects, subjects of other abnormal blood conditions, and those with normal blood. Dr. Barnett recounted in detail clinical cases in which the venom solution had been used to control hæmorrhage in hæmophilics of the most pronounced type following dental extractions, accidental wounds, and from epistaxis. In epistaxis light anterior plugging with ribbon gauze soaked in the solution had always secured immediate hæmostasis. Replugging had never been necessary. Following dental extractions, although a firm clot was always formed when the socket was plugged with venom-moistened wool, there was often difficulty in carrying the clot down to the bleeding point in the presence of an alveolar abscess. In these cases the dressing often had to be repeated several times a day for several days in order to control the hæmorrhage until the septic condition cleared up. The use of a specially made dental plate, to retain the dressing and maintain pressure, had proved valuable in such cases. The use of the venom solution rendered the extraction of teeth from hæmophilics a relatively safe though still serious operation. In dressing wounds, gauze moistened with the solution was applied and pressure maintained to secure temporary hæmostasis until the clot was formed. The possibility of hæmorrhage recurring later made skin sutures inadvisable. In abnormal blood conditions other than hæmophilia there were satisfactory reports of the use of the venom as a hæmostatic in purpura, leukæmia, and aplastic anæmia; the only case in the speaker's personal knowledge was that of a boy with purpura hæmorrhagica in whom epistaxis had been stopped on several occasions. In subjects with normal blood the venom solution had been used in dentistry and general surgery. It had been employed constantly in the dental department at St. Bart.'s for six or seven months and it had only failed twice. In one of these failures it was found that the excretion of ascorbic acid in the urine was below normal; this was probably a case of subclinical scurvy. A private dentist had found the venom particularly useful in stopping the slight bleeding that often delayed the completion of dental fillings, particularly those below the gum-margin. In general surgery it had been employed by Prof. G. E. Gask to stop capillary oozing after breaking down adhesions from the surface of the liver and after stripping the capsule from a kidney. Mr. A. M. Boyd had used it successfully after tonsillectomy.

SECTION OF STATE MEDICINE

AT a meeting of this section on May 24th, the president, Dr. J. D. ROLLESTON, being in the chair, a discussion on

Epidemiology in Country Practice

was opened by Dr. W. N. PICKLES, who gave an account of observations during a period of more than 20 years on the spread of infectious disease in a number of rural parishes in the still isolated district of Wensleydale. The records of mortality in the parish register of the once flourishing market town of Wensley, now shrunk to the measure of a little village, threw, he said, a dim but suggestive light on past epidemics, e.g., the visitation of plague in 1563, which probably had much to do with the decline of the town, while a note on small-pox in 1841, written by a rector, strongly impressed the value of vaccination. Life in many rural villages follows a more orderly routine and is lived in a more circumscribed orbit than in populous places, and village doctors are able to gain a detailed knowledge of the lives, loves, hopes, and avocations of most of their patients. In the elucidation of individual problems of the origin and spread of infection this knowledge often affords help denied to those working in the din and turmoil of a city practice. Dr. Pickles urged all similarly placed observers to bring forward their results, since it is only by the summation of many observations that the full value of this opportunity of adding to our stock of knowledge will be elicited. With the help of his daughter, Dr. Pickles has kept careful records and charts of every individual case of infectious disease that has come under his notice, and, aided by an intimate personal knowledge of most of his patients, he has been able to observe a uniformity in the incubation period of certain infective diseases strongly suggesting that the limits set out in text-books may be too wide. Certain cases of measles, in which almost the precise moment of the sole opportunity for infection could be definitely fixed, had an incubation period of exactly 12 days. In an epidemic of catarrhal jaundice in 1929–30, out of a population of 5700 at risk, 250 were attacked.

Of the 118 patients personally attended by Dr. Pickles, the charts relating to 23 in whom it was possible accurately to trace the chain of infection, strongly supported an incubation period of about a month, though there are, he thinks, two forms of this disease, one with an incubation period of only 2-5 days. His observations suggest that its infectivity is low and that the period of infectiousness is short. Careful observation of the alarming but transient symptoms of a disease up till then unknown in the district, enabled Dr. Pickles and his partner, the late Dr. Dean Dunbar, to identify it as epidemic myalgia or Bornholm disease. Dr. Pickles also brought forward observations in support of the belief that herpes zoster and chicken-pox are variants of the same disease. But while the Wensleydale villages are still comparatively isolated and remote, the centralisation of schools has afforded opportunities for the dissemination not only of knowledge but also of infectious disease. A zealous teacher, not realising she was suffering from influenza, in a single morning gave rise to 78 cases in an area up till then free from the disease. In an outbreak of Sonne dysentery, it was invariably the children attending school who first became ill in each of the families affected.

The President, Sir William Hamer, Dr. S. Monckton Copeman, and others took part in the discussion. The work of Dr. Pickles reminded Dr. J. A. Glover of a cross between that of Hippocrates and of Gilbert White, and Dr. P. Stocks spoke of the compound solution of antibodies which passes for normal serum in town-dwellers. Dr. E. W. Goodall was not prepared to abate the orthodox latitude of incubation periods. Surgeon Captain S. F. Dudley agreed, but regarded the study of infection in a comparatively natural population as of great value. Prof. M. Greenwood underlined the "fundamental" importance of such work which he considered comparable to that of William Budd and entitled to the widest publicity. The study of the natural history of epidemic disease was of first-class importance; more and more recorded observations of this kind were needed. The communities under Dr. Pickles's observation being less artificial than either mouse herds or ships' companies, deserved the closest study.

CHELSEA CLINICAL SOCIETY

At a meeting of this society held on May 21st at the Rembrandt Hotel, with the president, Dr. Charles Sundell, in the chair, a discussion on

Sexual Problems in General Practice

was opened by Prof. Millais Culpin. The first sex problem in practice, he said, was the practitioner himself. Just as there were practitioners temperamentally incapable of evaluating psychoneurotic symptoms and who therefore never heard them, so there were practitioners who, by their attitude, warned off any attempt to seek their advice on sex difficulties. Any doctor who was unable to ask a question about details of sex life without lowering his voice had better leave the whole subject alone. A practitioner who said he had never met a case of sexual perversion confessed to a personal inhibition. Some difficulties were purely artificial. The problem of sex education for the young only existed in the mind of the adult. There was no problem, therefore, if parents were free of taboo and answered questions with as little emotion as they would give answers about growing potatoes. Once a child had accepted the taboo, a barrier was built up, and this must be recognised by the practitioner, who could rarely penetrate it. To find out what a boy of 12 knew about sex was generally impossible, and the attempt might be recommended to the authors of little books on "What a boy of 12 should know." Adolescent girls might be asked: "Do you want to know?" and if the answer was "No," it must be accepted. If it was "Yes," the frankest possible explanation should be given, not omitting the emotional urge. To present the sexual act as a physiological process for the purpose of impregnation would make emotional difficulties worse. The adult who declared that he had known nothing of sex till the age of 18 was not uncommon. The state was probably a physiological dissociation, and was often associated with a rich unconscious phantasy life.

Masturbation was coming to be regarded as a normal phase of sex development, which made the handling of patients easier. Solemn warnings and attempts at restraint produced lasting harm. Impotence had such varied causes that every case was a separate problem. A conscious or unconscious attitude to sex as something shameful and almost sinful offered an obvious point of attack, and a discussion of the patient's upbringing might reveal twisted views. In impotence, however, the œdipus situation often called for full psycho-analysis; it was indicated by the patient's placing women in the two classes of angels and inferior beings. The worst problem was offered by the healthy woman married to an impotent man who regarded his impotence as a virtue. The practitioner in such a case should never approach the husband on the subject, nor should he tell a woman that her nervous symptoms were due to her husband's impotence. That they are her way of reacting to the situation may be true and an understanding of that view may help her. Frigidity was often part of a psychoneurotic condition and might react to the same treatment. Vaginismus was hysterical.

Homosexuality was often felt as inevitable and unquestionable, but the subject might be unscrupulous or filled with horror at himself. The second type could be helped by discussion, for he was a very isolated individual. Women rarely sought treatment for homosexuality and rarely felt distress at it. The question occasionally arose whether homosexuals ought to be school-teachers. If the condition was recognised and could be frankly discussed by the person concerned, there was less danger. Psychotherapy was not a magic wand, and was useless unless the homosexual wanted to be put on the other track. Generally, when it came to the point, he did not.

DISCUSSION

Dr. Joseph Geoghegan divided sex problems into two classes: departures from ordinary sexual behaviour, such as impotence, homosexuality, and frigidity; and departures from ordinary social behaviour involving problems of everyday life. The doctor got to know of these things through being more than a mere doctor. A very sound rule was to consider that one would not oneself want advice. The difficulty should be surveyed with common sense. Advice should not be given. Everybody was abnormal and apt to project his or her difficulties and moral standards. Principles were for oneself; charity for others. The best thing that the general practitioner could do was to be kind, and to send the patient to somebody who understood the subject better.

Dr. Travers Smith stressed the importance of not telling a woman that the sudden appearance of a neurosis was due to the impotence of her husband.

sometimes not felt at all sure of himself, purely as a result of fatigue.

Dr. A. P. GIBBONS told of a man who was charged with being drunk in charge of a car on the evidence of several police officers. He was driving and ran his front wheel into a temporary wooden island, which caused the car to skid. The speaker found a recent abrasion on the man's scalp, caused probably by his head striking a part of his car. The accused elected to be tried at the sessions, and when the speaker mentioned the abrasion the case was stopped and the man acquitted. In another case concussion probably played a part. Magistrates were not always easy to please. In one case his partner certified that a man was very decidedly drunk, and the magistrate asked what tests he had used; when told there was no need for tests, he said he could not convict a man on such evidence. On the next occasion his partner applied every test he knew, and the magistrate said, "If you had all that difficulty in proving the man was drunk, he could not been have so very drunk, after all."

Dr. P. B. SPURGIN spoke of the inhibitory effect of alcohol. Under its influence a man might well be more reckless for a time, and give the impression that he was a better driver than he actually was. He protested against the idea that the function of the police surgeon was to assist the police to convict.

The PRESIDENT said that a police officer who found a man suffering from shock, short of concussion, owing to an accident, might well believe him to be drunk. There was danger in trusting to this first evidence. Cyanide poisoning was not so infrequent as was sometimes thought; death might not follow for some time after taking the poison, especially if the preparation had been kept for some time.

MANCHESTER MEDICAL SOCIETY

The Black Death in England

AT a meeting of this society held on May 1st, Dr. J. E. SPENCE said that the term "Black Death," though later in origin, has now become distinctive of the great plague of the XIV century. England was at that time a feudal State, in which the King was the absolute owner of the land. This was granted to the barons in return for homage and military services, and was subinfeudated by them to knights, whose holding was termed a manor. The manors were self-supporting and were worked in common by the villeins in return for their holdings. Although the villein was not a free man and suffered from many disabilities, knowing no luxury, he was far from a slave. His lot was little worse than that of his lord. The towns of that time, with few exceptions, were merely overgrown villages. Sanitation was unknown, disease rampant, and mortality high. But the people enjoyed their simple pleasures and recreations, and were perhaps very little less happy than the town-dweller of to-day.

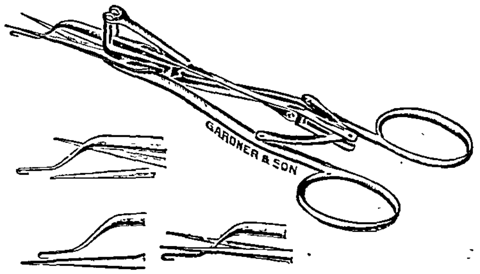
The Black Death was plague of the bubonic and pneumonic type. Originating at Caffra on the Black Sea in 1346, it spread first to Constantinople, and then by the maritime trade routes along the Mediterranean to this country, which it reached in August, 1348. It began in Dorset, and spread rapidly, reaching London in October and the north of England in the early part of the following year. It attacked especially the young and vigorous, and caused death in from twelve hours to three days. A distinctive feature was hæmorrhage from the lungs in addition to the buboes. Estimates of the mortality vary considerably, since mediæval chroniclers were extremely inaccurate in their estimates of large numbers, but research among diocesan records has shown that 44 per cent, of the clergy died of the plague, and this figure is probably approximately accurate for the people as a whole. As the population at that time was about 4½ millions, it is probable that the number who died was about 2 millions.

The havoc caused was enormous. Villages were abandoned, manors uncultivated, grain rotted in the fields, and the cattle roamed at will untended. Wages rose, and labour could not be obtained to cultivate the land profitably, hence an impetus was thus given to sheep farming, which required less labour; and the manorial system was gradually superseded by the letting of land to farmers.

NEW INVENTIONS

IRIDECTOMY SCISSORS

THE accompanying illustrations will show clearly the principles and the action of the iridectomy scissors which is essentially composed of an iris hook mounted on a pair of iris scissors, and operating on a combination of the principles of the grafting scissors and of StClair Thomson's tonsillotome. When the blades of the scissors are separated, the iris hook is thrust downward and forward between and below the blades of the scissors: on closing the blades again, the iris hook is first drawn backwards and then lifted above the level of the scissor blades which close below it at a convenient level to make a neat coloboma. For example, in making the preliminary iridectomy for a cataract extraction, a firm grip of the conjunctiva having been taken with the fixation forceps, and the linear incision completed, the iridectomy scissors are taken up with the thumb and ring finger in the handles, the index-finger placed on top of the instrument which is steadied against the side of the middle finger; the tip of the middle finger is rested on the eyebrow, and, the blades of the scissors being widely opened, the hook is entered into the wound and advanced till the edge of the iris engages; the scissors are then closed when the hook is automatically withdrawn and the iridectomy completed by the closing of the scissor blades. The lens can then be extracted in the usual way. Thus the whole operation is completed by the operator himself without the interference of an assistant, and without letting go the fixation forceps or moving the fixing hand in any way; further, the hook avoids the pinching of the iris in forceps which so often causes spasm or squeezing of the eye.



The instrument must not be used through a narrow incision for a simple iridectomy, for there is not enough free give of the corneal edge to allow of the hook lifting for withdrawal; it is apt to catch on the upper edge of the wound, and cannot be turned over to avoid this.

Messrs. J. Gardner and Son, 32, Forrest-road, Edinburgh, have kindly made the instrument for me. It may be made with straight blades, or curved, which would be more suitable for deep-set eyes.

WM. Y. TURNER, M.A., M.B., Ch.B.,
D.T.M. & H. Camb.

He did not think it was much use treating homosexuals, for whom nothing but prolonged psychoanalysis was any good. He cited a case of a woman who had vomited regularly every evening at 7 P.M., the time at which her husband came home. She had consulted 15 doctors, none of whom had thought to elicit the fact that she was sick of the sight of her husband, whose impotence had disappointed her of children. As soon as this had been made clear, the vomiting had ceased.

Dr. N. L. Lloyd pointed out that there must be some value in the universal sexual taboo, although society might have misinterpreted or misapplied it.

Dr. Halls Dally observed that co-education was more advanced in America than in this country, and that the general opinion seemed to be that it was better for girls than for boys, who tended to become less manly. Petting parties might not be a serious evil.

Mr. F. J. Ridley cited the case of a left-handed boy who had had the fullest modern sex education including cattle breeding, but at 15 knew nothing whatever about sex. He had fallen back on the taboo and suppressed the objective lessons put before him.

MEDICO-LEGAL SOCIETY

At a meeting of this society held on May 23rd, with the president, Sir Bernard Spilsbury, in the chair, a paper on

A Police Surgeon's Problems

was read by Dr. T. H. Blench (Manchester). These problems, he said, were very varied and being personal were not to be solved by academic discussion. One of the most frequently presented was the degree of alcoholic indulgence which prevented the exercise of proper control over a motor-car. Among all the tests and conditions the police surgeon must keep his main duty in mind; the effects of alcohol were transient, and the point to concentrate upon was the difference between the person charged and the average normal person. When this conclusion had been reached the examination should be stopped. Consent to be examined implied sobriety, inasmuch as drunkenness destroyed consent. The function of the police was to protect the innocent, and the police surgeon should help in this. The examinee should be placed at his ease; there should be no atmosphere of hostility. He himself reduced his examination to the minimum: walking across the floor, standing with eyes shut, coördination test (nose-touching with finger), physical examination, and five minutes' talk. He did not require repetition of set phrases; over-anxiety might vitiate their value. A history of the accident would lead to inquiry as to injury, and in all cases the state of health was investigated. There was a popular idea that if a man had taken any drink before an accident occurred, an accusation of having been under the influence of alcohol was bound to follow. Alcohol was sometimes taken to counteract the effect of shock; whether pure shock might simulate drunkenness could be verified in accidents to teetotallers. There were confirmatory possibilities by testing for alcoholism in the blood, urine, breath, or even the cerebro-spinal fluid, but to submit a person to these tests without his consent might be an assault. It was wrong to allege that the duty of the police surgeon was to support the opinion of the police.

Turning to other problems Dr. Blench said the investigation of sudden death gave opportunities for hard thinking and logical induction. Suicide by cyanide poisoning was found chiefly among persons who used that drug, such as jewellers, photographers, chemists. Some little detail would often give a clue to the person's mental condition. DeQuincey, in his "Murder as a Fine Art," said that the cut-throat was often something of an artist; in one case of murder related by Dr. Blench a young man had inflicted with a razor such a cut 4 inches deep severing the carotids and the larynx; yet the girl walked fifty yards after it. In a case of burglary a bitten apple was left behind, and a smart police officer became suspicious of a man who had lost a tooth. A mould of his mouth was found exactly to fit the apple, and the man was convicted. On the other hand, the production of minute measurements was apt to bore the court. When new methods of detection were introduced there was the danger of over-emphasis. Laboratory investigation should supplement not replace clinical methods.

Mr. Claud Mullins, speaking of charges arising out of motoring offences, admitted that when the influence of alcohol was alleged he paid as much attention to the evidence of the police officer who saw the defendant immediately after the accident as he did to the police surgeon who did not see him until some time afterwards. He always considered these charges with the greatest care, and in four years no one charged with such an offence had left his court without a verdict against him. The Act of 1930 was very explicit: "in charge of a car while under the influence of drink or drugs to such an extent as not to have proper control." This was a very high standard. He was in the habit of putting a homely and searching question: "Would you have liked him to drive you home?" He feared the wording of the new Act had not yet percolated through to advocates generally. When the fumes of the car were alleged to be the cause of the man's helpless state, he always asked whether the windows were up, and if so why.

Mr. Roland Burrows, LL.D., remarked that the answer to the question whether a person was drunk should depend on the circumstances. If asked whether a man was too drunk to go upstairs to bed, or to go home, or to do what he was in the habit of doing in the course of his business, frequently the answer must be No. The criterion was different when in charge of a car. In such a case Mr. Mullins's questions "Would you care for him to drive you home?" went to the root of the matter. It was possible for a man to recover partially from his alcoholism if there was a considerable interval before the police surgeon's examination. Conversely some men did not behave erratically until some time after taking alcohol.

Dr. Caldwell Smith stressed the influence on the accused person of nervousness when he found himself charged at a police station; it might modify his answers to a considerable extent. In borderland cases, when the police surgeon was called up in the night, it was wise for him, after a rapid examination, to ask for his decision to be postponed until the morning. With regard to poisoning by fumes from the car, it was important to remember that the driver might not know what was amiss; he just felt unwell and soon was leaning helplessly over his steering wheel.

Surgeon-Captain M. H. Knapp, R.N., said that forty years ago the crucial question asked in cases of alleged drunkenness was, "Is he fit to go up aloft?" With regard to men driving a car well at the beginning of a journey and being apparently under the influence of alcohol at the end of it, he thought a man might well pull himself together for the first stage, and later let himself go, with the result that he crashed.

A member drew attention to the factor of fatigue. After a long motor run, especially at night, he had sometimes not felt at all sure of himself, purely as a result of fatigue.

Dr. A. P. GIBBONS told of a man who was charged with being drunk in charge of a car on the evidence of several police officers. He was driving and ran his front wheel into a temporary wooden island, which caused the car to skid. The speaker found a recent abrasion on the man's scalp, caused probably by his head striking a part of his car. The accused elected to be tried at the sessions, and when the speaker mentioned the abrasion the case was stopped and the man acquitted. In another case concussion probably played a part. Magistrates were not always easy to please. In one case his partner certified that a man was very decidedly drunk, and the magistrate asked what tests he had used; when told there was no need for tests, he said he could not convict a man on such evidence. On the next occasion his partner applied every test he knew, and the magistrate said, "If you had all that difficulty in proving the man was drunk, he could not been have so very drunk, after all."

Dr. P. B. SPURGIN spoke of the inhibitory effect of alcohol. Under its influence a man might well be more reckless for a time, and give the impression that he was a better driver than he actually was. He protested against the idea that the function of the police surgeon was to assist the police to convict.

The PRESIDENT said that a police officer who found a man suffering from shock, short of concussion, owing to an accident, might well believe him to be drunk. There was danger in trusting to this first evidence. Cyanide poisoning was not so infrequent as was sometimes thought; death might not follow for some time after taking the poison, especially if the preparation had been kept for some time.

REVIEWS AND NOTICES OF BOOKS

Midwifery

Fifth edition. By Ten Teachers, under the direction of Clifford White, M.D., B.S., F.R.C.P. Lond., F.R.C.S. Eng., F.C.O.G. Edited by Sir Comyns Berkeley, J. S. Fairbairn and Clifford White. London: Edward Arnold and Co. 1935. Pp. 740. 18*s*.

Multiple authorship can be employed in two ways. It is usual to find that each chapter or part of a subject has been allocated to one writer. Not so with the Ten Teachers, one and all of whom accept responsibility for the work as a whole. Each method has its disadvantages, but without doubt the joint responsibility results in the production of a work of great value.

In the fifth edition of this work, which appears under the direction of Mr. Clifford White, its well-known characteristics remain unchanged. Certain additions merit attention, such as a new and remarkably clear diagram of the fœtal circulation, and paragraphs dealing with the physiology of menstruation, the toxæmia of pregnancy, pyelitis, and puerperal infection.

The book is perhaps less dogmatic than most, and especially is this noticeable in the matter of treatment. Thus throughout the book sentences occur such as "good results have sometimes followed this procedure, but it is only applicable to a certain few cases and the results have, as a whole, been disappointing." The impression formed is that the Ten have not always been in complete agreement, and that methods of treatment of unproven value have been inserted and assessed in such doubtful terms for diplomatic reasons. A student or practitioner would like definite guidance, but obviously it is impossible always to provide this. Nevertheless, the uncertain value of a particular treatment might in some places have been stated more clearly. The value of the book is probably greater than any of the preceding editions, and the publishers have maintained the same high quality of print and paper.

Treatment of Rheumatism in General Practice

Second edition. By W. S. C. Copeman, B.Ch. Cantab., M.R.C.P. Lond., Hon. Physician, B.R.C.S. Clinic for Rheumatism, Peto-place, Assistant Physician, West London Hospital, Children's Department. London: Edward Arnold and Co. 1935. Pp. 228. 9*s*.

In the second edition of this book a number of important additions have been made. Gold salt injections are deemed to be of definite value in carefully selected cases; the contra-indications, dangers of overdosage and so forth, are clearly set out. The use of histamine is discussed both as a general treatment by subcutaneous injection and as a local application by means of ionisation. Bee-venom and intravenous calcium therapy are also described. In the chapter on manipulation the use of evipan as an anæsthetic is strongly recommended. The ease with which anæsthesia is induced by means of this drug is of advantage both to the patient and to the operator, particularly in view of the fact that often a second or third manipulation is necessary. The paragraph devoted to short wave diathermy is regrettably short, although its importance is admitted. A longer discussion on the possibilities of this form of treatment would have been welcomed, despite the expense of installation which is at present an obvious drawback to its general use. A chapter on the subject of prognosis and end-results makes it clear that quick results are not to be expected; rheumatic patients must be prepared to undergo treatment over periods of weeks or months before they can hope for real and lasting benefit. Dr. Copeman believes, and many authorities would agree with him, that "Prognosis in the rheumatic diseases is twice as good to-day as it was 30 years ago, not so much owing to the introduction of new methods as to the renaissance of interest in the subject."

The 1934 Year Book of Pediatrics

Edited by Isaac A. Abt, D.Sc., M.D., Professor of Pediatrics, Northwestern University Medical School; Attending Physician, Passavant Hospital. With the collaboration of Arthur F. Abt, B.S., M.D., Associate in Pediatrics, Northwestern University Medical School; Adjunct Attending Pediatrician, Michael Reese Hospital. Chicago: The Year Book Publishers, Inc.; *London*: H. K. Lewis and Co. 1935. Pp. 541. 9*s*. 6*d*.

Whilst no collection of abstracts, however carefully selected, can give more than a very uncertain indication of the year's progress in any subject, the Pediatric Year Book suggests an almost bewildering amount of activity. Needless to say, much of this activity gives rather the impression of Brownian movement than any ordered journey to any known destination; there is the usual collection of rarities, from purulent parotitis to rupture of the liver; there are the inevitable banalities culled from presidential addresses and leading articles. But amongst these are such investigations as those carried out on the prophylaxis and treatment of anterior poliomyelitis and whooping cough, which, though still in the experimental stage, give some cause for optimism. It would perhaps be churlish to point out that a disproportionate amount of attention is here devoted to the contributions of American authors, but we should certainly have to adopt an unduly modest view of English pædiatrics if we were to regard this Year Book as fully representative. Considered as a heterogenous collection of abstracts, however, most of which give a reasonably fair synopsis of the original, this book will be found to serve a useful function. The references appear to be quoted accurately and in consistent form, and the illustrations are for the most part well chosen, though not all printed the right way up.

French Medicine

By Prof. Laignel-Lavastine, Professor in the Medical Faculty in Paris; Secretary-General of the International Society of Medical History; and Dr. Raymond Molinery, Gold Medallist of the Academy of Medicine; Member of the French Society of Medical History. Translated by Dr. E. B. Krumbhaar, Professor of Pathology, University of Pennsylvania. New York: Paul B. Hoeber, Inc. 1934. Pp. 187. $2.50.

The American who remarked of the British Isles that they have no climate, only samples, would probably have been tempted to pass a somewhat similar judgment on this book. This in praise rather than in criticism of it. For sampling is in itself excellent when exercised with the discretion which the authors have shown. They have undertaken to compress the history of French medicine into the *Clio Medica* series of primers on the history of medicine issued by the publishers, and any gratified ambition to deal with the subject in an encyclopædic frame of mind would have been disastrous. The portraits chosen for reproduction are, on the whole, illuminating, with the exception of certain groups of members of the Academy of Medicine whose appreciation requires a magnifying glass. The history is brought up to the present post-war period, with Leriche making surgery more and more physiological, and the leading physicians thinking more and more in the terms of surgery. The authors agree that French medicine is not what it was. "Its great periods of expansion were in the Middle Ages, the 13th century, after Louis XIV., and especially in the 18th and early 19th centuries . . . . now it only has one voice in the crowd. It must be admitted at least that in medicine its voice is always plain." An index of personal names and another index of subjects add greatly to the usefulness of the book.

Christine Murrell, M.D.

Her Life and Work. By Christopher St. John. Preface by Lady Barrett, C.H., C.B.E., M.D., M.S. London: Williams and Norgate. 1935. Pp. 133. 5*s.*

Christine Murrell entered the medical profession at a time when women doctors were still looked at askance, not only by their male colleagues, but by the general public. There were, it is true, quite a number of outstanding women practising in London, but the medical woman of that time had to have an ability considerably above the average in order to achieve success. This Dr. Murrell had without doubt, and in addition she had a forceful—though kindly—personality. She took a deep interest in all branches of her profession, though psychological illness and child welfare were the subjects that made the strongest appeal to her.

Dr. Murrell was fortunate in escaping the financial perplexities which confront most young people of either sex when faced with the prospect of establishing themselves in a good class practice. After gaining some valuable post-graduate experience she and her friend Dr. Honor Bone started practice together with such success that assistants and later junior partners had to be enlisted to cope with the work and thus one of the old-established London firms of medical women was founded. Dr. Murrell was an ardent feminist of the genial sort that has no antipathy to men—indeed she had perhaps more men than women among her personal friends. Her innate sense of justice led her to realise, however, the many difficulties which then, and even now, beset the professional woman when she tries to take her place alongside of her male colleagues. Her work for the Medical Women's Federation, of which she became both treasurer and president, was invaluable, but it is rather as a keen and prominent member of the British Medical Association that she will be remembered. She took an active part in the Association's medico-political activities, was the first woman member of its council, and it was as an outcome of the high esteem in which her work was held that she was elected last year, with the support of the Association, as a direct representative to the General Medical Council. Unfortunately the illness from which she died had already incapacitated her, so that she was unable to take her seat on the Council.

Dr. Murrell had a strong, resolute character, and did not tolerate fools gladly. She liked to get her own way, but even those who did not always agree with her admitted that her way was usually the best way. The affection and admiration that she inspired is shown by the fact that two memorials are being raised to perpetuate her memory. The first is a fund, which aims at equipping part of a new infant welfare centre at the St. Marylebone Health Society in her name, and the second project, is to form, under the auspices of the Medical Women's Federation, a Christine Murrell Memorial Fellowship for post-graduate study for young women practitioners. This volume provides a third and an appropriate memorial, and Miss St. John has given a charming and sympathetic account of an outstanding woman.

Lumbalanästhesie in der Geburtshülfe und Gynäkologie

By Dr. E. Preissecker. Vienna: W. Mandrich. 1934. Pp. 76. Fr.50.

This small book will appeal to those who are working on the physics and pharmacology of spinal analgesia more than those whose concern with the subject is mainly clinical. The latter will, however, be interested in the author's observation that headaches after spinal injection are less frequent in pregnant women than in others. On the other hand, he has noticed that the lowered blood pressure, often a trouble after spinal injection, is accentuated by the reduction of the abdominal pressure after delivery. It is especially for Cæsarean section that he values intraspinal analgesia, and he relates a series of 150 cases with four deaths, only one of which can fairly be attributed to the anæsthetic. This is, he finds, a lower mortality than that following general anæsthesia in similar circumstances. There were six deaths among the 150 infants, but in four of these he exonerates entirely the spinal injection. The biochemistry of the spinal fluid is discussed in detail, and a chapter is devoted to the pharmacology of drugs used for endothecal injection. The book is carefully compiled and contains much valuable information.

Urinary Analysis and Diagnosis

Sixth revised edition. By Louis Heitzmann, M.D., formerly Professor of Pathology and Bacteriology, University School of Medicine, Fordham, New York. London: Baillière Tindall and Cox. Pp. 385. 22*s.* 6*d.*

This is a large book on a rather small subject, which should find a place on the shelves of every clinical pathological laboratory and side-room; in somewhat small bulk and at a correspondingly lesser price it might have made appeal to medical practitioners, students, and nurses alike. The material is well and clearly set forth; the illustrations are lavish and serviceable. On the whole the teaching is reliable; in the section on extraneous matter in the urine it is unfortunate that the illustration described as showing "normal fæces" depicts among other things, a fragment of striated muscle—one of the few findings in the fæces invariably significant of some morbid condition. If the book were somewhat reduced in bulk it would make an even wider appeal.

Clinical Laboratory Methods and Diagnosis

By R. B. H. GRADWOHL, M.D., Director of the Gradwohl Laboratories and of the Laboratories, St. Louis County Hospital. London: Henry Kimpton. 1935. Pp. 1028. 36*s.*

THE design of this book is ambitious and its scope considerable. No procedure which a worker in a hospital laboratory may be called upon to perform escapes notice; and useful sections will be found on the identification of poisons, the performance of post-mortem examinations, the preparation of extracts for allergy tests, and on many other procedures rarely present in works on general laboratory technique. Unfortunately, in common with other authors of similar works, Dr. Gradwohl has found difficulty in deciding whether he would write a text-book of pathology or of laboratory procedures. Where he roams into the field of pathology he is not a particularly illuminating guide; even on the purely practical side his descriptions of technique and methods are not always clear. More rigorous editing is required throughout. Slips such as that which occur on p. 512 should have been avoided. Here in one line it is stated that "neutral fats and fatty acids are soluble in ether; combined fatty acids or soaps are not," and a little further down that "neutral fat, free fatty acids and soaps are soluble in ether." This sort of careless writing is likely to discourage the inquiring student.

This book is attractively produced; the illustrations—colour plates, line drawings, and photographic engravings—are among the best we have met with in any book of this sort. The author makes a well-deserved acknowledgment of the skill of Mrs. Addine G. Erskine who drew and arranged them.

Bee Venom Therapy

By BODOG F. BECK, M.D. London: D. Appleton-Century. 1935. Pp. 238. 18*s.*

IN books as well as in buildings the Americans are inclined to do things on the grand scale. From its respectful dedication "To the Pathfinders of Bee Venom Therapy" to its 11 pages of bibliography this work is a magnum opus in miniature and, could they only know of it, would make every right-thinking bee carry her sting more proudly. The author's industry has brought together information about every possible aspect of bee venom, and the only criticism is that he has failed entirely to separate the grain from the chaff. A critical summary at the end of each chapter would have greatly increased the value of the book. In spite of this fault, a great deal of valuable information has been collected. The first part of the book has chapters on the medical history of the bee, animal venoms, bee venom and its effects, the results of bee-stings, sensitivity, the treatment of bee-stings. Part II. is an enthusiastic account of the results of apitherapy in arthritic and rheumatoid conditions.

We learn that the effective part of the venom is a very toxic organic base, as yet unidentified, and that the irritation of the sting is said to be due to volatile oils. In the production of injectable bee venom these oils and the protein are removed, the latter process being a secret of the manufacturers; 25,000 bees are required to produce one milligramme of pure venom. A study of the surprisingly large number of fatal cases caused by bee-stings leads to the conclusion that allergy must play the greatest part, and the sensitivity may vary very greatly between different individuals and in the same individual at different times. Adrenaline preparations seem to be the favoured remedy for severe general effects. All local treatments of bee-stings are, in the author's opinion, unsatisfactory, and we must comfort ourselves with Cicero's advice that "to mind a bee-sting is a truly feminine trait."

As to the value of bee venom therapy in arthritis and allied conditions, no scientific appraisal of its value is attempted, but at least all the information is given from which the inquiring reader can form his own conclusions.

Clinical Pathology and the Technique of Collecting Specimens

By WILLIAM SMITH, M.A., M.D., B.Chir., Pathologist to the Miller General Hospital, Greenwich. London: J. and A. Churchill Ltd. Pp. 158. 5*s.*

Dr. Smith seems to have been impressed by the number of specimens unsuitable for the particular examination demanded which are submitted to his laboratory. He has therefore written this book to explain to practitioners and others concerned with the taking of specimens the way in which these should be collected. The intention is laudable; one can but wish him luck. But we fear that to secure the correct approach of the practitioner to the laboratory will require something more than a series of lectures on the collection of specimens. Such lectures will not destroy the faith of those who, having withdrawn specimens of blood and urine in the most correct manner, submit them to the pathologist in the hope that his incantations will solve clinical problems.

The book should be of value to nurses and laboratory technicians entrusted with the collection of specimens in the wards.

Lodgings for Twelve

By H. H. BASHFORD. London: Constable and Co. 1935. Pp. 311. 7*s.* 6*d.*

Dr. Bashford's prose has a quality which recalls that of Dr. John Brown and gives conscious delight to the discriminating reader; the other sort of reader will get almost as much pleasure from these essays without knowing quite where it comes from. The author introduces us to people he has met as a child of the late Victorian era, as a boy emigrant farming in Canada, as a medical student at the largest of the London teaching hospitals, as a locum tenent, and in "a more or less open house" of his own. Many men of varied experience will have met equally interesting people and have passed on without appreciating the full flavour of their peculiarities; few indeed would be able to convey this flavour to others with such a sure touch. We enjoyed all the essays immensely and reopened the book to read again about Dr. Coley and Dr. Knight—a contrast in general practitioners, about the gallant life of Aunt Felicia, and about Lucy Saltoun; rereading both for the charm of the writing and for the wickedly apt sketches of two or three fellow students of Dr. Bashford in the very early years of this century. We looked in vain for encounters or incidents arising during his long medical career in the civil service, and can only hope that these are being reserved for publication at such a time, even if this is still remote, when they can neither infringe conventions nor cause embarrassment to colleagues or successors.

THE LANCET

LONDON: SATURDAY, JUNE 1, 1935

TO COUNTER THE ILLS OF SOCIETY

NATURE recognises no watertight compartments and yet presents so vast and complicated a structure that man's mind cannot compass its entirety. Pasteur said, "There is only one way of seeing things rightly and that is seeing the whole of them"; but specialism has become a necessity if knowledge is to increase. In no branch of applied science is this dilemma more evident than in medicine; we are continually faced with the danger that a pursuit of scientific truth may impair our sense of perspective, so that eventually we shall come to resemble the man who, knowing more and more about less and less, ended by knowing everything about nothing. The moral is that pragmatism still has a claim and that the patient is greater than his disease; and in his Heath Clark lectures Prof. MAJOR GREENWOOD has been pointing this moral with characteristic lucidity and incisiveness. His two addresses on the Temperamental Factor in Industry were in fact concerned less with industry than with life as a whole. Industry is but a function of man's economic existence; it depends on factors external to itself and it exercises its influence throughout our modern society: and if Prof. GREENWOOD chose to employ a limiting title for his discourse it would be a mistake to ignore his words simply because we may have no immediate industrial affinities. What he said on these two occasions carries a message which none of us can properly neglect.

GALEN taught the indissoluble unity of mind and body, and to this extent we are urged to return to the spirit of the ancients. We are reminded that the temperamental constitution of man is a personal characteristic which determines not only his way of life but the course and prognosis of his diseases, and we are shown how in more recent times medicine has tried to materialise—and to interpret in physical terms—something which is essentially psychological. The physician who sees in statistical data clear-cut and ready-made paths to the surmounting of individual difficulties is forgetting that statistics deal with group phenomena and with probabilities that are rendered valid only when the group is of a size statistically significant. If in addition he forgets that the science of living, with all its emotional actions and reactions, is still in the phase of gestation he is doing science a disservice and himself an injury. It is the fusing of emotion and reason in balanced harmony that makes for vivid and creative life; and medicine has not entirely ignored this fact. At the same time the mere realisation that patients have important emotional reactions is valueless unless one can see how these reactions are "touched up" by circumstances: the mere addition of psychological medicine to the medical curriculum will avail little unless we aim at making the student interested in the economic, educational, and industrial background of the patient's life. Prof. GREENWOOD says that people are unhappy in mind under the modern industrial system; H. G. WELLS says that the mass of mankind, halting in intellectual puerility, constitutes the greatest menace to civilisation; Dr. CRICHTON-MILLER, in the address appearing elsewhere in this issue, says that the ultimate stewardship of mental health lies with the individual himself. In these three statements we not only get a glimpse of the track that medicine must follow—namely, in helping to readjust the patient's psychological balance—but we see also how we must bring to bear on educational technique the results of psychological research. If man is unhappy under a system and if that unhappiness produces, as it now certainly does, varying and widespread effects on body and mind, then we require an adult-minded, psychologically poised and intellectually courageous body of men and women to bring about a change.

Medicine on its physical side can still be practised within four walls; but on its mental side—on the side that views the whole man as something greater than his symptoms—its boundaries are coextensive with life itself. Let us specialise by all means; let everyone contribute something detailed, exact and necessarily limited to the pool of knowledge; but at all costs let us also maintain at a high level the general culture of those who practise medicine. Only in this way can we possibly meet the demands that modern life places before us and help to lighten the burdens that it lays upon our patients. Miss MAY SMITH, D.Sc., in the concluding lecture of this series, showed how specific, and (to some) apparently trivial, maladjustments can cause a flare-up of emotional conflict. She believes that if we could break away from the idea of "nervous" breakdown and call it "emotional" breakdown we should be helping to clarify our pathology. Dr. CRICHTON-MILLER, on the other hand, with less regard for current feelings, would call them all "mental." Either term will serve, however, provided only that it will widen and deepen understanding of the present situation. Temperament is not yet amenable to statistical evaluation; admittedly knowledge is greatly lacking. But we know already, without room for doubt, that a very high proportion of the sickness wastage in what we term an industrial society results primarily from temperamental maladjustments and from the influence of modern life on minds which have little real insight into themselves. We are passing through one of the great upheavals in cultural history, when events move fast and changes are both profound and rapid. Besides helping people to understand themselves the medical men and women of to-day are in duty bound to pay attention to the world around them, so as to be able, wherever possible, to counter the ills and contribute to the moulding of society, that it may conform more nearly to the needs of man.

THE LISTER INSTITUTE

THOSE who are inclined to deplore the academic preoccupations of workers in medical research institutes not attached to hospitals will find little reason for discontent in the annual report of the Lister Institute for 1934–35. It so happens that this year many of the results obtained by experiment in the different departments are likely to be directly applicable in the practice of preventive or curative medicine. For example the successful passage of vaccinia virus in a cell free medium, though still capricious, gives hope of a revolution in the future methods of cultivation of this virus, and the use of elementary body suspensions as a substitute for ordinary vaccine lymph is also of the utmost practical interest. Animal experiments have shown these suspensions to be in every way comparable to ordinary lymph; they possess the advantage of bacteriological sterility and represent the virus in the purest form available. It is proposed to make human vaccinations with these suspensions when opportunity offers. An estimation of the potency of human convalescent sera in poliomyelitis is being made in collaboration with the Danish State Serum Institute; the neutralising value of a number of samples of serum from Danish cases of poliomyelitis at different periods following recovery from the disease is being tested on monkeys and compared with serum obtained at Elstree by immunisation of horses with the virus. The collaboration of workers from the institute with clinicians has suggested that the cause of acute rheumatism may be a virus and their preliminary observations have already been printed in our columns. We have also published observations on the new antigen of *B. typhosus*, named Vi because of its close association with virulence, and to the clinical confirmation of the importance of the presence of Vi antigen in vaccines injected prophylactically against infection by *B. typhosus* and in sera used in the treatment of infection by the most common type of this bacillus.

The investigation on male adult rats of the scope, applicability, and trustworthiness of the balance-sheet method for estimating the biological value of proteins has been completed. With this method, in which measurement is made of the power to maintain nitrogenous equilibrium over short periods, the influence on biological value of altering the proportion of protein in the diet has been studied in the proteins of wheat, maize, and milk. In all cases an increase in the proportion of protein in the diet has been found to lower the biological value—i.e., its utilisation has been less economical. A special study has also been made of caseinogen, both before and after undergoing the processes of heating and purification, as ordinarily carried out before inclusion in diets used in vitamin work. Purification or prolonged heating at 120° was found to have no significant effect on the biological value; heating for long periods at 150°, however, lowered both the digestibility and the biological value. The vitamin-B complex has received considerable attention, with the result that vitamin B_2 is now held to have two constituents, both necessary for the maintenance of growth and health; the one, a heat-stable lyochrome pigment, appears to be connected with a generalised skin affection seen in young rats deprived of vitamin B_2; while the other is a supplementary substance (B_6) which occurs in yeast extract and appears to be specially required for the prevention of the more florid symmetrical dermatitis called "rat pellagra" and which is regarded as the analogue of the human disease. If, however, B_6 has entered the lists, B_4 has left them, for no confirmation could be found of the existence of any antineuritic factor other than B_1. The occasional incidence of local reactions had been reported following the injection of staphylococcus toxoid for the immunisation of patients. The toxic filtrate obtained by the method of cultivation in a cellophane bag is relatively more free from non-specific constituents than that which is prepared from the broth-agar medium, and as the product has been proved experimentally to be an efficient immunising agent, this technique has been adopted for the staphylococcus toxoid supplied for clinical tests. The statement that globulin preparations from human placentæ contain immune substances which have a neutralising action on the virus of measles is being examined. A clinical trial of two batches of human globulin solution, each of which has been prepared from a large number of placentæ in order to equalise the varying antibody content, will be undertaken in the autumn, when a recrudescence of measles is expected to occur.

Only a few even of those researches with a direct clinical bearing have been mentioned; the prophylaxis of tetanus, the mechanism of urine production, the symptoms which follow adrenalectomy in rats, and the effect of gamma ray irradiation on cultures of a protozoon, are among the many other problems under investigation. More than 30 papers have been published from the institute in various scientific journals during the year and several others are now prepared for press. It is clear that under the able direction of Prof. J. C. G. LEDINGHAM, F.R.S., the staff of the four departments of the institute are extending their activities in every direction which shows promise, and by collaborating with each other and with workers elsewhere are making the utmost use of the available accommodation and resources.

THE THYROID GLAND IN HEALTH AND DISEASE

NINE years ago Prof. HARINGTON announced his synthesis of thyroxine, and the biochemists, with others who were in a position to appreciate it, experienced the thrill of satisfaction that is evoked by a beautiful and valuable chemical achievement. Since then he has been occupied with the more difficult task of elucidating the chemical changes involved in the physiological and pathological activity of the thyroid cells—deciphering the chemical language in which the thyroid talks. His Oliver-Sharpey lectures, appearing in our last issue and in this, embody some of his most recent results, and introduce certain speculations that may lead to further discoveries. Thyroxine, it is now agreed, is the important vehicle of the gland's influence, both in health and in Graves's disease, and PLUMMER's theory, that the diseased thyroid produces an abnormal and peculiarly toxic variant of thyroxine, is now being abandoned both in this country and in America. All the manifestations of hyperthyroidism, not excluding exophthalmos, can be produced experimentally by thyroxine, and all the signs and symptoms of myxœdema can be removed by it. Its action in raising the basal metabolic rate of myxœdematous patients has indeed been used as a method of physiological assay, and has helped to reveal a curious discrepancy. The activity of a sample of thyroid substance given by mouth is about twice as great as that of the thyroxine it contains, and seems to be related to the total iodine content of the sample —not, as might have been expected, to the thyroxine-iodine content, which is approximately half the total. Thyroxine in combination appears to be more potent than free thyroxine; and it must be in combination, not merely by simple peptide linkage with some other amino-acids, but with other amino-acids plus diiodotyrosine, which is the iodine-containing thyroxine-precursor found along with thyroxine in the thyroid gland. The last point is as yet hypothesis, but if it is sustained it will influence the method of assay of thyroid preparations for pharmaceutical purposes. In America the activity of a preparation is taken to be proportional to its total iodine content; the last edition of the British Pharmacopœia attempted greater accuracy by taking thyroxine-iodine content as the measure, since it can be a variable fraction of the total. It now seems that the American method may be after all a nearer approximation to the truth.

From the biochemist's point of view the first riddle of hyperthyroidism is the familiar and mysterious effect of iodine. The normal thyroid passes through functional cycles, from rest to activity, with hypertrophy and hyperplasia of its cells and outpouring of secretion, and thence by involution to a colloid state in which the secretion is largely stored. An active or overactive stage can be induced in animals by restriction of their iodine intake or by partial extirpation of the gland, and is present in man in hyperthyroidism. In all these conditions iodine administration causes the gland histologically to involute, and in human hyperthyroidism involution is accompanied by a diminution in intoxication. Prof. HARINGTON is inclined to accept MARINE's view that this effect is largely mechanical, the distension of the follicles with colloid hindering the absorption of secretion by the lymphatics, though the idea that some secretion is diverted into colloid storage until the storage room is taken up would equally well explain the apparently temporary nature of the clinical effect. In either case the characteristic feature of the thyroid in hyperthyroidism is not its anatomical structure but its functional " diarrhœa " of secretion, which may be a little modified but is not fundamentally altered by iodine. MEANS and LERMAN[1] agree fully with that general conception, but from a recent study of over 500 patients in the thyroid clinic of the Massachussetts General Hospital conclude that iodine has more than a merely temporary effect; accurate observations indicate that it applies a gentle but steady inhibition to the outpouring of secretion, so that the " diarrhœa " proceeds with its characteristic spontaneous waves of varying intensity but at a somewhat lower level so long as iodine is being given. This differs from HARINGTON's view that the iodine effect is purely temporary and cannot be elicited a second time, and it is important from the theoretical side that the issue should be settled. Practically and clinically however, it is clear that iodine can only ameliorate, and that to a limited degree; it does not strike at the prime cause of the trouble.

Can the prime cause of the trouble, then, lie outside the thyroid? Is the " diarrhœa " of the gland due to an external stimulus? The thyrotropic hormone of anterior pituitary extracts comes at once to mind, for it can produce in animals both hyperplasia and increased secretion of the thyroid. But it does so only for a week or two, and after longer continued injections loses its effect. J. B. COLLIP, seeking to explain this, has been able to produce an antiserum to the hormone by prolonged administration of it to a horse, and has adumbrated a whole series of anti-hormones which are to play opposite the recognised hormones on the endocrine stage. Prof. HARINGTON shrinks from this alarming mating of immunology with endocrinology, and wonders whether—perhaps even hopes that—the " antibody " may prove to be a hormone from the suprarenal cortex or some equally respectable source. Meanwhile the cause of Graves's disease still eludes us, and most likely " involves complexities . . . as yet unsuspected." Not a few of those, we may suppose, will be unravelled by the precise and painstaking methods of the biochemist, so well exemplified in Prof. HARINGTON's researches.

◆

AT a general meeting of the Royal Society of Medicine held on May 21st, Sir StClair Thomson was unanimously elected an honorary fellow. It was the only new British nomination this year. With a membership now approaching 5000, the Society has only 23 British honorary fellows. Sir StClair Thomson is the first laryngologist—indeed, we believe, the first specialist—on whom this distinction has been conferred. The society has 27 honorary foreign fellows and of these one, viz., Prof. Chevalier Jackson, is a laryngologist. No other specialty has received such distinction. The foreign fellows elected this year are Profs. Sigmund Freud (Vienna), Joseph Jadassohn (Zurich), Edouard Jeanselme (Paris), G. R. Minot (Harvard), and R. F. J. Pfeiffer (Breslau). Prof. Jeanselme, as our Paris correspondent noted last week, died before receiving the honour.

Colonel W. P. MacArthur has been appointed to succeed Major-General R. M. Ainsworth as commandant of the Royal Army Medical College on Sept. 26th next.

ANNOTATIONS

UNEMPLOYMENT AND MEDICAL BENEFIT

We referred recently to the problem which arises out of the National Health Insurance Act of 1932, under which many insured persons who have been unemployed for a long period are expecting to lose their pension rights at the end of 1935. The Government's new National Health Insurance and Contributory Pensions Bill, which was introduced on May 23rd, is intended in a large measure to remove this fear and to put on a new permanent basis the means for continuing the pension rights of the unemployed and to protect them against a reduction or suspension of cash benefits under the health insurance scheme. All insured persons on ceasing to be insurably employed have at present a free insurance period averaging twenty-one months. The Bill provides that during this period the insured person will be fully protected for pension and health insurance benefits. Beyond the period of grace any person who has been continuously insured for ten years before the date on which he ceases work, and is now unable to obtain insurable employment, will have his insurance continued from year to year and, however long this ensuing period may be, he will be sure of his pension rights, of medical benefit, and of additional treatment benefits. But he will not be entitled to cash benefits, for which, however, he can requalify if he re-enters insurable employment and pays twenty-six insurance contributions within two years. The charge in respect of pensions will fall wholly on the pensions account, but it is anticipated that the existing financial provisions will suffice and that no additional demand will be made upon the Treasury. As regards the remission of arrears of contributions, the cost, some £1,500,000 per year, will be met from an arrears fund which will be provided as to 50 per cent. by an annual Exchequer grant and as to the remainder by a levy on the approved societies—and in effect upon the insured population. Each society will contribute according to the amount of unemployment and will receive back a grant in proportion to the amount of unemployment among its own members; the arrears fund will thus be in effect a means of sharing the losses due to unemployment. The solution of the difficulty has been achieved broadly upon the lines set out on p. 1128 of The Lancet of May 11th, with the modification that instead of the whole cost falling upon approved societies half of it will be met by an Exchequer grant. It is matter for encouragement that since 1932 the percentage of unemployment among persons insured under the health provisions has decreased from 14½ to 13.

Before the Bill was introduced the Government actuary reported that in respect of the Pensions Acts solvency would be achieved until 1946, with a small margin, if the annual contributions by the Exchequer were maintained at the sums prescribed for that period by the Statute, under which in 1934–1935 the amount is £13,000,000 rising by £1,000,000 a year until 1942–1943 when it will remain stationary for four years at £21,000,000. If the average rate of unemployment for the next ten years should prove to be 13 per cent., the average rate for the last financial year, the additional cost involved under the new Bill, so far as pensions is concerned, will be covered by the pensions account until March, 1946. It is interesting to note that the finances of the pensions scheme have benefited by the fewer deaths among men and especially among married men, with the result that fewer claims have been made than had been expected. This profit must, however, have been diminished by the longevity of widows.

NARCOTIC TRAFFIC IN EGYPT

The annual report of T. W. Russell Pasha on the work of the Egyptian Narcotics Intelligence Bureau for 1934, if not as sensational as usual, is full of statistical information, heavily documented and illustrated. It deals less with external illicit traffic and more with rounding up small traffickers in opium, heroin, and hashish throughout Egypt. Smuggling still continues, despite the vigilance of the police under Russell Pasha's able direction; Suez is a hotbed of the traffic and it is alleged that not less than 3000 out of a population of 40,600 are in some way connected with the contraband trade. Numerous seizures of hashish and heroin are reported, often concealed with an extraordinary amount of ingenuity. A new feature is the growing habit of resorting to "black tea" as a narcotic—that is, tea repeatedly boiled until a heavy dark brown residue is obtained possessing narcotic and toxic properties which render the addict incapable of work and result in digestive disorders. This black tea habit is said to have arisen from the restrictions placed upon the use of hashish; the peril arising from the latter, by way of cigarette smoking (marihuana) in the United States and Canada, is now engaging the attention of the Opium Advisory Committee at Geneva. The Egyptian Government would support a world-wide outlawing of Indian hemp, but this apparently would not be acceptable to the Indian Government, owing, it is said, to its association with certain religious rites of the Hindus.

FRACTURE DISLOCATION OF THE LOWER RADIAL EPIPHYSIS

Injury to the lower epiphysis of the radius is comparatively common in boys. The lesser degrees of displacement give rise to little or no anxiety, but every now and again a case is seen with a considerable backward dislocation of the epiphysis, usually associated with splintering of the shaft posteriorly. The greater the surgeon's experience the less will be the confidence with which he attempts a closed reduction; for it will often fail even after repeated attempts under full general anæsthesia. On the other hand, although a poor position is the final result of treatment, ultimate deformity of the wrist which can be traced to previous epiphyseal injury is *not* a condition met with clinically. Struck by the fact that he has never seen such a deformity in his work in the out-patient department of the Boston City Hospital, A. P. Aitken [1] has re-examined 58 patients at periods of 2–9 years after their discharge from treatment for various degrees of fracture and fracture-dislocation of the lower radial epiphysis. Of the 58 patients, 8 were girls and 50 boys, and this corresponds with the experience of other observers; thus E. Bergenfeldt [2] described a series in which there were 118 boys and 18 girls. In 2 of Aitken's cases the injury was bilateral; in 28 the posterior edge of the diaphysis was damaged, and in 19 there was an associated injury to the ulnar styloid. No attempt at reduction was made in 17, but in all the others the position was considered to require improvement. In 7 cases there were two attempts at reduction, and in 4 cases there were three. Osteotomy was carried out in 4 cases. The results of the 60 fractures, as estimated at the time of discharge from hospital, are summarised thus: normal to good position, 26; slight displacement, 20; fair to poor position, 14. At the time of re-examination 2–9 years later no deformity could be found in any of them, even when the original displacement had involved a quarter or half the thickness of the shaft. Malposition in this injury does not persist, and we seem to be safe in predicting that in two or three years at latest the normal relationship of epiphysis and shaft will be restored. The other question which Aitken investigated was the effect of epiphyseal injury on the growth in length of the radius. He found that premature ossification and retardation of growth did undoubtedly occur, but were on the whole negligible. Isolated cases have been reported in which conspicuous deformity persisted, but these he attributes to excessive damage at the time of injury. The injury must certainly be very severe, for osteotomy through the epiphysis had been performed in one of Aitken's patients without giving rise to any appreciable shortening, and repeated manipulation seems likewise to be harmless in this regard. Where shortening was measurable, it was only about 1/16 inch; in but one patient was it as much as ⅜ inch. A few cases, indeed, showed the opposite effect—a slight stimulation of growth.

[2] Acta Chirurg. Scand., vol. lxxiii., suppl. xxviii.; see The Lancet, 1934, i., 308.

It is interesting to note that these results agree with those reported by Bergenfeldt for radial epiphyseal injuries.[2] In view of the ultimate history of the cases Aitken has good reason for thinking that where one attempt at accurate reduction fails, repeated manipulation is unnecessary. He believes that the open operation of osteotomy is not justifiable.

AMERICAN COMMENT ON THE OSTEOPATHS BILL INQUIRY

IN his presidential address to the General Medical Council on Tuesday afternoon, Sir Norman Walker recalled the evidence which he gave before the select committee of the House of Lords when considering the registration and regulation of osteopaths. "I took the opportunity," he said, "to expound the merits of our British system of one register for qualified medical practitioners, and am hopeful that the system which has worked, and worked well, for nearly eighty years will be maintained." Sir Norman also recalled in his address the words of an earlier president, Sir Richard Quain, who forty-three years ago said it was recognised more and more every year that the Council is doing all in its power to secure the higher education of the profession, and to elevate and maintain its character in all that is essential in connexion with the welfare of the public. "In some other countries," Quain added, "these duties devolve on Government officials: happily here they are placed in our own hands. . . ." In a leading article in the current issue of the *Journal* of the American Medical Association, the editor remarks, "Great Britain seems to have realised the value of its own method of control," and he adds, with obvious regret, "Apparently it still requires some extensive education of both legislators and the American people to bring them to a realisation of the necessity for basic science legislation in this country." In America, in contrast to this country, the practice of healing is forbidden except to those who are registered, and consideration of this fact should, the *J.A.M.A.* says, emphasise to every intelligent person the necessity for developing in the United States, through the establishment of basic science laws, a minimum standard of education for all who propose to heal the sick, regardless of the method by which such healing is to be brought about. There is in the leading article a thumbnail picture of the result of the inquiry which, it is remarked, "occupied a good many days and cost a lot of money. It brought out the fact that the proponents of the legislation were not capable of framing a definition of osteopathy that would distinguish it from other healing cults. It made clear the fact that the osteopaths claim that their art and practice cover the whole field of medicine, and that osteopathy is based on a pathology and a theory of causation which are peculiar and in no sense of the word established. Although the osteopaths were willing to accept certain limitations of their work and to stress spinal manipulation, they claimed the right to use surgery of all degrees and drugs of many varieties. Indeed, they claimed equally to prevent disease by spinal manipulation and to limit infectious disease by this process."

THE BLINDING FILARIA IN AFRICA

BLINDING infection with the filarial worm *Onchocerca volvulus* has been found by J. Bryant[1] to be a major health problem in that part of the Sudan which drains into the Bahr-el-Ghazal and the Sudd regions of the Upper Nile. An endemic blinding disease seems to have been present locally in this province for at least sixty years, but it now has a wide though patchy distribution, and where it exists at all its incidence is astonishingly high and increasing. The most striking instance quoted is that of a tribe on the Lau river, Yirrol district, among whom the disease was unknown in 1933 and where now 8 per cent. of the adult taxpayers have had to be exempted from taxation because of blindness. This last takes two forms. One is a keratitis with lack-lustre, and later vascularised and opaque, cornea, iritis and choroiditis, with slow obliteration of the pupil, and with microfilariæ present throughout the eye; it is accompanied by intense photophobia and may progress slowly for years. The second is initiated by a short-lived lacrymation, passing in two or three weeks into night-blindness and reaching its climax in two or three months, by which time blindness may be complete, or partial, or only complained of at night; the lesions are irregular atrophy of the retinal layers, particularly of the nerve-fibres, with pigment masses in or on the retina, but no microfilariæ in any structure of the eye. Yet there is reason for believing that this second form is onchocercal in causation; for whereas among 750 adults paraded for sleeping sickness inspection only 9 per cent. showed manifestations of onchocerciasis, the incidence of such manifestations in cases of "Sudan blindness" (as Bryant calls it) was 58 per cent. *Simulium damnosum*, an established carrier of onchocerca infection in Africa, swarmed in these parts, the foci of disease being rocky streams commonly in the forest country. The search for onchocerca as the cause of the local blindness was made on the suggestion of J. Hissette,[2] who has shown what a scourge this worm has become within the last few years by producing wholesale blindness of inhabitants of certain parts of the Belgian Congo.

It may be recalled that E. Brumpt, after investigating the blinding filaria of Guatemala, held th[illegible] *it* differed—somewhat in morphology and striking[illegible] ocular effects on man—from *O. volvulus* for l[illegible] in Africa, and that he named the New World form *O. cæcutiens*. As to morphology, J. H. Sandground,[3] after examination of onchocerca worms from various sources in impressive numbers, has found no constant difference between those from Guatemala and those from Africa, while as to lesions, the facts quoted above show that the production of ocular lesions does not, in fact, distinguish from one another the forms found in the two hemispheres. *Onchocera volvulus* is, then, the valid name for this parasite of man. What causes it to produce in certain parts of the world these devastating effects on the eye is unknown. Richard C. Strong[3] notes that in Guatemala, which place has given the worm its title of "blinding," only 5 per cent. of the infected suffered from ocular lesions. In the affected spots in the Sudan, however, the percentage of infected so suffering is clearly many times greater, and is showing a disquieting rate of increase. Accordingly the obligation on its Government to take active steps for the closer investigation and stronger control of this infection is of corresponding and pressing urgency.

THE LAURENCE-MOON-BIEDL SYNDROME

THE association of obesity, hypogenitalism, mental retardation, and polydactyly with retinal pigmentation may at first sight seem at least as improbable as the existence of Othello's men whose heads do grow beneath their shoulders. On embryological grounds it is hard to link the mesenchymal abnormality which results in the polydactyly and other skeletal defects with the retinal and diencephalic defects which are epiblastic in origin. The complete syndrome is, indeed, of extreme rarity, and in some of the family groups recorded is only seen spread through different members of the family. Cockayne, Krestin, and Sorsby[4] have reviewed the literature of this curious condition, adding two family groups to the 30 or so examples already published. Out of the first family group of ten, three (and possibly four) members were found to be affected, whilst of the second group of four members three were affected. In the first instance no one patient showed the full syndrome, although all the components of the syndrome were found between the three affected patients. In the second group the eye changes were those of cerebromacular disease. The authors discuss the possible relationship of the condition with juvenile amaurotic idiocy (Batten-Mayou disease), since certain characteristic eye changes may occur in both; but there are, as they point out, definite differences in the onset, course, neurological signs, and sex incidence, here being an excess of males affected with the urence-Moon-Biedl syndrome, whereas no such onderance exists in juvenile amaurotic idiocy. also conclude from the evidence available that Laurence-Moon-Biedl syndrome is inherited as autosomal recessive. In the complete sibships recorded, information as to the presence or absence of consanguinity of parents is given in 23 instances; of these, 6 were the result of first-cousin marriages and 3 of second-cousin marriages, whilst in the remainder there was no blood-relationship. Thus 43 per cent. were derived from first- or second-cousin marriages. There is no instance of the parents being affected with the syndrome. The authors also incline to the suggestion made by Rieger and Trauner[5]—and elsewhere independently by Cockayne[6]—that the epi- and mesoblastic elements of the syndrome are both recessive and due to mutations in two genes in the same chromosome.

MALARIA IN CEYLON

A RECRUDESCENCE of malaria has been reported this spring in those parts of Ceylon affected by the epidemic. The symptoms have been of a milder type generally, and cerebral cases and convulsions have been rare. No information is available at present to indicate whether there has been a fresh increase in mosquito-breeding, leading to reinfections, or whether these cases are simply relapses. That the recrudescence has not been maintained is shown by a reduction in the number of reported malaria deaths from 19,059 in March to 15,933 in April. The full history of the epidemic will be awaited with great interest; both from the epidemiological standpoint—which should provide Colonel J. G. Gill, with striking parallels and equally striking contrasts with his experience in the Punjab—and from the standpoint of treatment. The situation has afforded an opportunity for the clinical test of the latest remedies upon a grand scale, and the issues at stake, as between the growers of quinine on the one hand and the manufacturers of synthetic antimalarial drugs upon the other, are of immense importance. It is to be hoped that any conclusions reached upon these issues may rest on a truly scientific assessment of the evidence.

DENERVATION OF THE KIDNEY

RENAL sympathectomy, on which Mr. S. Harry Harris, of Sydney, opened a discussion at the urological section of the Royal Society of Medicine last week, has only recently attracted attention in this country. Mr. Harris has been carrying out denervation of the renal pedicle for over eight years and is in a position to speak of the limitations of the operation as well as of its uses. The condition in which he finds it act most favourably is one for which he has coined the somewhat awkward term "renal sympathetico-tonus." How this overaction of the sympathetic nerves of the kidney is brought about he does not know, but its results can now be described with accuracy. Mr. Harris divides them into three stages.[7] First, a phase of irritability when the patient complains of colicky pains and the pyelogram shows a state of systole, the pelvis and calyces being contracted and the renal papillæ flattened out by the increase of intrapelvic pressure. Hæmaturia, which is a not infrequent complication of this phase, probably results from congestion caused by the contraction of the intrinsic muscles of the kidney. The second stage is one of exhaustion or diastole. Instead of occasional attacks of colic, the patient has a dull aching in the loin, increasing occasionally to a sharper pain. Pyelography shows the renal pelvis and calyces in a state of diastole. The third or final stage may be described as retention with overflow; Harris compares it to Hirschsprung's disease of the large bowel. In all three stages the injection of eserine has a favourable effect, relieving the spasm of the first and—provided there is no organic obstruction—provoking the dilated pelvis to empty itself in the later stages. After describing the technique of denervation of the pedicle, he deprecated the indiscriminate use of the operation. Subsequent speakers in the discussion endorsed this risk; Mr.

[7] Harris, S. H.: Renal Sympathectomy and Renal Sympathetico-tonus, THE LANCET, Feb. 23rd, 1935, p. 424.

Hugh Lett foresaw a danger of denervation being used for the innumerable cases of backache of doubtful origin seen in out-patient departments. Mr. J. B. Oldham, of Liverpool, confirming Mr. Harris's findings in general, mentioned other conditions in which theoretically sympathectomy might be serviceable. The renal pedicle, he said, contained three types of nerves, those running to the blood-vessels, those supplying the musculature, and sensory nerves. Since the majority of the nerves terminating in the vessels were vasoconstrictor, division would bring about a condition of vasodilatation. It was therefore logical to employ renal sympathectomy in reflex anuria, and after pyelo-nephro-lithotomy in order to increase diuresis and diminish the risk of a recurrence of stone. As, however, he had found that diuresis was preceded by a period of reduced secretion, he no longer considered sympathectomy appropriate in the treatment of reflex anuria. If, as Mr. Harris suggested, hæmaturia might be a result of contraction of the intrinsic musculature of the kidney, denervation was a possible treatment for that mysterious condition, essential hæmaturia. He agreed with Mr. Harris that the operation should cause no ill-effects, although in three cases in which he had attacked the pedicle by the abdominal route acute dilatation of the stomach had followed. In the near neighbourhood of the renal pedicle were sympathetic fibres running to other viscera; it must be remembered that both the diseases and the results of the operation might not be limited to the kidney itself. Exaggeration of the knee-jerks might, he thought, be a useful sign in diagnosis. The consensus of those taking part in the discussion was that denervation of the renal pedicle in appropriate cases was a valuable asset to surgery. Animal experiment and human experience both showed that the kidney suffered in no way from being deprived of its nerve-supply. The functional complications to which some writers have drawn attention are evidently considered rare. Indeed we have heard of their being likened to the Russians who came through England at the beginning of the late war; everyone, it was suggested, had heard of them but very few had seen them.

NEW JOURNALS OF ANÆSTHETICS

WITHIN the last few weeks two new periodicals wholly devoted to anæsthetics have made their appearance on the continent, one in Italy and the other in France. Their production is evidence of the importance now attached in those countries to studies which until recent years were pursued in English-speaking countries almost exclusively. Germany has for some time had her *Schmerz Narkose-Anæsthesie*, but there, as elsewhere in Europe, local anæsthetics were so largely preferred to general that the study of anæsthesia as a whole, and the education of specialists, were behind what had been done in Great Britain, Australia, Canada, and the United States. The situation is now rapidly changing. Although it will probably be a good while before there are on the continent many practitioners devoting themselves entirely to anæsthetics, there are already a number who, though mainly surgeons or physicians, have undertaken research in connexion with, or have seriously practised that branch of medicine. The result has been in France the formation of a French "Society of anæsthesia and analgesia" whose official organ is one of the new journals referred to above. The first issue of *Anesthésie et Analgésie* contains a paper by the editor, Dr. R. Monod, on the aims of the society and the means by which it hopes to attain them, while Prof. E. Desmarest contributes a capital review of the present state of opinion and practice regarding anæsthetics. There is also a full account of the articles of the society and of its first session. Three original communications and a good recent bibliography complete an issue which sets a high standard.

RHEUMATISM UNDER REVIEW

INCREASING interest in the health of the industrial worker has meant increasing—though inadequate—attention to the rheumatic diseases which impair his efficiency. In the United States the American Association for the Study and Control of Rheumatic Diseases arranges conferences as a meeting-place for all medical men concerned in the study of arthritis, and the proceedings of its first annual congress, held at Cleveland last summer, have been reported at length.[1] In his presidential address Dr. Ernest E. Irons, of Chicago, rightly pointed out that the magnitude of the suffering and disability caused by arthritis offers a challenge to the medical profession and the public. Chronic arthritis is to be thought of as a disease that affects the body as a whole rather than the joints alone, and every patient presents a special problem. A division of arthritis into two clinical groups, atrophic and hypertrophic, is accepted as convenient, but the rôle of focal infection in their ætiology is variously assessed. Indeed, no clear opinion emerged from the congress as to whether the joint lesions are due to a bacteræmia, or are metastatic, toxic, or allergic. Dr. Arthur Steindler, in a careful study of 4339 patients, concluded that foci of infection were present in 17 per cent. of cases both of atrophic and hypertrophic varieties: these foci, in descending order of frequency, were in tonsils, teeth, accessory nasal sinuses, biliary system and genito-urinary tract. Removal of foci was followed by subsidence or decided improvement in a quarter to a third of the cases, but many relapsed, and when followed for a year only 8–15 per cent. of the patients were found to have gained real benefit. On the nature of the causative germs in these foci even greater divergence of opinions is found. It is commonly agreed that the streptococci are the predominant bacteria present, but very few workers accept a "Streptococcus rheumaticus" as probably responsible. The diversity of the members of the streptococcus group, their apparent ability to change in cultural characters, especially in their variable hæmolytic action upon blood corpuscles, makes experiment difficult. Further, there is lack of uniformity in the results of blood culture. A more suggestive finding is the presence of positive skin reactions to streptococci, and serum agglutinins for hæmolytic streptococci, in patients suffering from chronic atrophic arthritis. "I do feel," said Dr. C. W. Wainwright, "that the skin reaction is the most definite evidence of hypersensitiveness obtainable." When attempts are made to turn these results to practical use with injections of vaccines, it can only be said, however, that their value remains unproved.

A factor that has been emphasised more generally of late is the nutritional one. Rheumatic patients are often found to be taking a deficient diet; they favour sugars and sweets, refined cereals and white bread. Many workers accordingly ascribe the increasing incidence of rheumatic disease to a change not only in quantity but in quality of the foods usually taken, and emphasise especially an insufficiency of the vitamin B group.

Removal of foci was followed by subsidence or decided improvement in a quarter to a third of the cases, but many relapsed, and when followed for a year only 8–15 per cent. of the patients were found to have gained real benefit. On the nature of the causative germs in these foci even greater divergence of opinions is found. It is commonly agreed that the streptococci are the predominant bacteria present, but very few workers accept a "Streptococcus rheumaticus" as probably responsible. The diversity of the members of the streptococcus group, their apparent ability to change in cultural characters, especially in their variable hæmolytic action upon blood corpuscles, makes experiment difficult. Further, there is lack of uniformity in the results of blood culture. A more suggestive finding is the presence of positive skin reactions to streptococci, and serum agglutinins for hæmolytic streptococci, in patients suffering from chronic atrophic arthritis. "I do feel," said Dr. C. W. Wainwright, "that the skin reaction is the most definite evidence of hypersensitiveness obtainable." When attempts are made to turn these results to practical use with injections of vaccines, it can only be said, however, that their value remains unproved.

A factor that has been emphasised more generally of late is the nutritional one. Rheumatic patients are often found to be taking a deficient diet; they favour sugars and sweets, refined cereals and white bread. Many workers accordingly ascribe the increasing incidence of rheumatic disease to a change not only in quantity but in quality of the foods usually taken, and emphasise especially an insufficiency of the vitamin B group.

---

[1] Jour. Amer. Med. Assoc., 1934, ciii., 1732, 1801, 1883.

Treatment, it was suggested, must take account of all these factors. The diet must be high in calories and rich in vitamins, with plenty of red meat, starches, fresh fruits and vegetables, and including yeast, wheat germ, and cod-liver oil. General measures of hygiene—rest, fresh air and sunlight—are important; and obviously infected foci should be removed. Sedatives may be needed to secure adequate sleep, and blood transfusion is often useful, especially before operations for removal of foci. The care of the joints themselves, it should be recognised, demands much more than a routine. The changes in them are due to the disease, to muscle spasm, and to inactivity in a position of deformity; hence rest and the avoidance of trauma, freedom from weight-bearing and some degree of immobilisation, with prevention of changes from disuse, are the indications, and they must be met by counterpoised motion and active exercises. It was pointed out that pain during exercise is of little or no significance provided it does not continue *after* exercise. Physical therapy, splints, specific exercise, and supports need thought and planning. Local heat and ionisation with choline derivatives are often helpful, while acetylsalicylic acid is a standby for pain. No mention was made in the debates of gold therapy as advocated by Forestier and others.

PNEUMOCOCCAL PERITONITIS

Candolin has lately made an elaborate study of 97 cases of pneumococcal peritonitis seen in Finland, and although his conclusions are not very novel the fact that they are reached from so large a series is in itself important. As has now been pointed out repeatedly, the disease is one especially of small girls. Candolin offers no explanation why this should be so: he is not at all impressed with the results obtained from examining vaginal smears; nor does he regard the vagina as a likely portal of entry for the pneumococcus. Of the cases in this series 64 per cent. were girls under ten years of age, and until the age of 30 females still showed a preponderance, after which there was a fairly even distribution between the sexes. Only a quarter of the patients were adults. The treatment given, in all but 11 cases, was operative, and as a rule the operation was done in the initial stage of diffuse, or non-localised, peritonitis. Such treatment is not what is usually accepted as the best, but the measures adopted are often determined rather by the difficulty of diagnosis than by the surgeon's preference for them. Weighing the pros and cons of early operation, Candolin thinks on the whole that delay in operating is rarely justifiable in adults, in whom the diagnosis must often be conjectural, to say the least. In children there may be more reason to suspect the disease, and the clinical picture may be definite enough to justify a differential diagnosis from appendicitis, which at this time of life is the only condition likely to cause confusion. In girls up to the age of ten pneumococcal peritonitis and appendicitis occur in the proportion of 1 : 3.

In pneumococcal peritonitis, Candolin finds, the onset tends to be suddener, and sometimes there is a history of previous catarrh. The patient's general condition is apt to seem worse than would be expected from the local signs in the abdomen. The white blood count is somewhere about 20,000, and a blood examination is helpful particularly in long-standing cases in which tuberculosis is suspected. Herpes and cyanosis, when present, are suggestive of pneumococcal peritonitis, and in about 70 per cent. of cases diarrhœa is a more or less conspicuous symptom. Unfortunately, however, in pelvic appendicitis too—and this is just the variety in which accurate diagnosis is liable to cause difficulty—diarrhœa is comparatively common. In pneumococcal peritonitis abdominal examination reveals a diffuse swelling, not at first obvious, which is doughy to feel and meteoric on percussion; usually there is no very definite resistance of the muscle wall, nor any localisation of signs and symptoms. Unfortunately, again, from the point of view of diagnosis, Candolin found that when one side was apparently more implicated than the other it was the right (30 per cent. of cases). A pronounced distension may be present from the start. Of complications those in the lung, and especially pneumonia, were fairly common, but Candolin seems to regard them as true complications, and not as part and parcel of a generalised pneumococcal septicæmia. Of his 97 cases 32 are noted as having some form of lung affection, 16 of these being pneumonia; and of the 16, there were only 4 with signs of pneumonia from the onset. Generalised septicæmia is reported in only 8 cases.

The mortality was rather higher in adults (16 out of 24, or 67 per cent.) than in children (40 out of 73, or 55 per cent.); of the 11 patients who had no operation, all but one died. Operation in the "diffuse" stage of the peritonitis showed a mortality of 62 per cent.; while of the cases left without operation at this stage (some eventually opened; some treated without operation) 46 per cent. died. In cases not treated by primary laparotomy and surviving this stage to develop an abscess which can be drained later the prognosis is of course comparatively good; thus those operated on in the stage of abscess-formation in Candolin's series had a mortality of 13 per cent. But, as he is at pains to emphasise, it is not fair to compare this figure directly (as has been done by some authors) with the figure for operation in the "diffuse" stage, since at the time of deciding whether or not to open the abdomen at the onset of illness one does not know whether the patient belongs to the group of possible survivors, or to the group who will die in the acute stage of the illness. As signs indicating a bad prognosis, he mentions a temperature above 40° C. (104° F.), a difference of more than 1·0° C. between the rectal and axillary temperatures, a pulse-rate above 130, albuminuria, absence of diarrhœa, intestinal paralysis, and the presence of a large number of bacteria in the exudate. Unilateral pneumonia did not seem to make the prognosis any worse.

DR. W. G. Savage, who has been elected to succeed Dr. Veitch Clark in October as president of the Society of Medical Officers of Health, has been county medical officer for Somerset since 1909. His name has long been associated with a national campaign for pure water, pure milk, and unadulterated food.

AN exhibition will be held at the Royal Society of Medicine, 1, Wimpole-street, London, on July 1st to 13th, of the works of members of the Medical Art Society, whose president is Sir Leonard Hill, and hon. secretary Prof. C. A. Pannett. Under the rules the works of art by members of the society, admissible to the exhibition, will be paintings, aquatints and mezzotints, drawings, etchings, and lithographs, statuary and plastic work in any medium, and carving. Illustrations of medical subjects will be included in the exhibition.

PROGNOSIS

A Series of Signed Articles contributed by invitation

LIV.—SUBACUTE COMBINED DEGENERATION OF THE SPINAL CORD

NEUROLOGICAL complications are present in at least 80 per cent. of all cases of pernicious anæmia (P.A.) when first examined. Occasionally the change is mental—varying in degree from irritability, altered temperament, and character, to the fully developed psychosis most commonly of the paranoid type; but the usual complication is subacute combined degeneration of the spinal cord (S.C.D.), heralded by *paræsthesiæ*—numbness, tingling, coldness—of the extremities and showing in the spinal cord evidence of diminished function of both the *posterior columns* —hypotonia with absent or diminished deep reflexes, impaired vibration, and positional sense in the limbs with resulting ataxia—and *lateral columns*—hypertonia with increased deep reflexes and extensor plantar responses. The physical signs vary, dependent on the relative intensity of involvement of the posterior and lateral columns.

Before 1926 S.C.D. was rightly regarded as an invariably progressive disease which proved fatal in two to three years. We are now able with efficient liver therapy not only to restore rapidly the blood picture in pernicious anæmia to normal but also to maintain it with continued adequate treatment at a normal level. Has this advance enabled us to modify our outlook in the neurological complications of pernicious anæmia?

GENERAL CONSIDERATIONS

The symptoms and signs of S.C.D. may result from lesions in (1) the spinal cord, and/or (2) the peripheral nerves, which play a rôle probably greater then we have hitherto recognised. Disturbance of the functions of these structures in P.A. can result from (1) the anæmia itself, with resulting defective nutrition of nerve elements; (2) neuronic disintegration due to either a toxic agent or the absence of some specific factor necessary for neural nutrition; and (3) areas of softening which result from small hæmorrhages or thromboses. Any of these pathological disturbances in the peripheral nerves is potentially curable—i.e., given time and adequate therapy restoration of function will occur. But in the spinal cord any of these pathological factors may leave irreparable damage. No regeneration occurs in the central nervous system; hence only those symptoms resulting from temporary loss of function in the affected area of the cord due to the first and second factors detailed above are potentially curable. That this second factor exists is evident from those cases in which S.C.D. precedes the development of anæmia. The evidence available does not suggest that it is identical with the P.A. factors or with any of the known vitamins. On general grounds, therefore, the maximum therapeutic response which we can hope to achieve is to remove those symptoms resulting from peripheral nerve lesions and from temporary loss of cord function due to the factors above discussed.

But the clinical position is complicated by two facts: (1) the same physical signs result whether loss of nerve function is temporary or permanent; (2) it is difficult to differentiate clinically between certain posterior column and peripheral nerve defects of function, for paræsthesiæ, hypotonia, absent deep reflexes, and various sensory disturbances with ataxia are common to both. Hence in any given case of S.C.D. seen for the first time it would appear impossible to foretell with accuracy the results of treatment. Certain facts, however, do emerge from observations of patients suffering from P.A. and S.C.D. who are kept under continued adequate treatment (and no treatment which permits the red blood-cells to fall below 5,000,000 can be regarded as adequate):—

A. In over 50 per cent. of all cases treatment is followed by marked subjective improvement—the paræsthesiæ disappear, the gait becomes steadier, and the patient stronger; in only a small percentage of cases (under 5 per cent.) is there definite objective improvement, as evidenced by the restoration of a normal flexor plantar response which was previously extensor or diminution in the area of vibration loss. In this connexion it is important to avoid that optimism which results from inaccurate interpretation of altered physical signs, for the deep reflexes may revert to what appears to be a more normal type by extension of the cord lesion—e.g., the diminished knee-jerk of a patient in whom the degeneration is advancing in the lateral columns may become brisker.

B. If symptoms of S.C.D. are absent in an established case of pernicious anæmia they rarely develop if the patient is kept under adequate liver therapy—i.e., the prophylactic value of adequate anti-anæmic treatment against the development of S.C.D. is established. On the other hand, the development of S.C.D. is from clinical observation an almost inevitable consequence of inadequate treatment of P.A.

C. The presence of sepsis—urinary, pulmonary, or skin infections—not only retards the return of the blood picture to normal in P.A., it tends to accelerate the rate of progress of S.C.D.

RATIONALE OF TREATMENT

As in many other nervous diseases, so in S.C.D. the permanent loss of function resulting from the disease may be partially compensated by re-education —e.g., Fraenkel exercises or orthopædic measures: the temporarily impaired nutrition of muscle and nerve is improved by physiotherapy; but the essential treatment must clearly aim at overcoming the causative factors. From the general considerations above outlined, particularly the absence of more detailed knowledge of the second factor (and it cannot be held that the advocates of iron and vitamin-deficiency theories have established their claims), the only factor which lends itself to treatment is the associated *anæmia*; but that this is of overwhelming importance is shown by the infrequency with which symptoms of S.C.D. develop with a normal blood picture.

The detailed treatment of P.A. by various forms of liver and stomach extract, &c., has been the subject of many papers to which reference can be made. It may be summarised by emphasising that intramuscular injections of liver extract combine the maximum efficiency with the minimum expense in restoring the blood picture to normal. Any active preparation—e.g., Campolon (Bayer), Hepastab (Boots), Hepatex I.-M. (Evans)—can be used. As a rule 4–6 c.cm. are injected daily for four to seven days, and then on alternate days until the blood picture is restored to normal. The maintenance dose—i.e., that which keeps the red blood-cells at over 5,000,000 per c.mm.—is then established; this varies with the individual, but averages 2–4 c.cm. every two to six weeks. Stomach preparations are preferable to liver extracts if oral therapy is desired.

CONCLUSIONS

1. When a patient with S.C.D. is first seen the combination of (*a*) profound anæmia with (*b*) marked subjective symptomatology is of favourable prognostic import. In these, treatment is likely rapidly to improve both the blood picture and the nervous symptoms. Young patients tend on the whole to respond better than old. Unfavourable signs are: (*a*) marked objective disturbance as evidenced by lateral column changes, with (*b*) a relatively slight anæmia; and (*c*) sepsis.

2. If the symptoms of S.C.D. improve pari passu with the blood picture in P.A. the prognosis is good, for, with the maintenance of a satisfactory blood picture, the development of nervous symptoms is in the vast majority of cases indefinitely retarded. It is well here to emphasise that the maximum improvement in the nerve symptoms may not occur for 9–12 months, although the blood picture is much more rapidly restored to normal, a fact easily appreciated when one remembers that peripheral nerve regeneration may be a necessary preliminary to recovery.

3. A patient with P.A. in whom S.C.D. has not developed is adequately protected against this complication by efficient treatment of the anæmia.

THE STEWARDSHIP OF MENTAL HEALTH *

BY H. CRICHTON-MILLER, M.D., M.R.C.P.
HON. SENIOR PHYSICIAN, INSTITUTE OF MEDICAL PSYCHOLOGY

DISEASE of the mind is a conception nearly as old as thought and language. But the health of the mind has been taken for granted until recent years. Psychiatry is a much older word than the phrase "mental health." And this is significant. We begin to talk and write about a concept only when we find that we cannot assume its permanence. Centuries ago men talked of "ministering to a mind diseased:" to-day we ask "Who is responsible for keeping a mind in health?" To-day there seems to be an increased interest in bodily fitness with more stress on individual responsibility. Alongside of this tendency, public opinion is accepting the idea that the community has a responsibility for conditions favouring health; witness the clearance of slums and the provision of playing fields. If the maintenance of physical health were universally regarded as the basic wealth of the community, we might reach a clearer understanding of how far society and how far the individual are respectively responsible for it.

If this difficulty exists in matters of bodily welfare, it is greatly intensified in the more subtle and complicated problem of mental health. The familiar tag about "Mens sana in corpore sano" is charged with fallacious reassurance. Some may keep the body fit and yet become insane; while others maintain astonishing mental vigour despite gross neglect of physical health. The problem is indeed subtle and complicated, and it is so partly because we hold very varied views about mental health. Let us approach it first from the community point of view. We might describe a healthy community as one in which the mental hospitals were nearly empty; the mental defectives reduced to zero; crime enormously reduced; suicides very rare. That is frankly Utopian, but if succeeding generations keep steadily in view this fourfold objective, progress will at least be more rapid than it is at present. Indeed, as far as the first and the last criteria are concerned, we are, at the moment, actually losing ground.

Attempts at Definition

If I were asked to define mental health I would confess myself defeated, but I am prepared to describe what the term conveys to me. I would describe the healthy minded man as one who combines personal harmony with social effectiveness in the following ways:—

1. He must have the will to live.
2. He must be able to enjoy all normal biological functioning.
3. He must have enough feeling of self-mastery to maintain adequate independence of circumstance and environment.
4. He must be ready to face conflict, internal or external, with a minimal recourse to evasion; or, in other words, he must be able to maintain subjective harmony with the least possible objective distraction.
5. He must have a scale of values whereby experiences and memories that have purpose and significance are preferred to those that lack them.
6. His social effectiveness must be characterised:—
    (*a*) By a reasonable confidence in his fellow-men.
    (*b*) By a broad toleration of human idiosyncrasies.
    (*c*) By that sense of social responsibility which only manifests itself in those who recognise in social contribution a prerogative rather than a duty.

It is clear that there can be no mental health where there is no will to live. The ability to enjoy normal biological functioning is also an obvious criterion of mental welfare; it matters not whether we are considering the girl with anorexia hysterica or the homosexual man. No one is mentally fit who lacks a reasonable degree of self-mastery. The young man who cannot face the simplest social gathering, and the woman who cannot bring herself to travel by underground, are cases in point. I have said that the healthy minded man must face conflict with a minimal recourse to evasion. This involves all tedium, frustration, insecurity, and vicissitude from which men try to escape by active distraction or passive anæsthesia. It comprises the youth who gambles because he is bored, the woman who drinks to forget her sexual conflict, the girl who develops asthma when she is jilted, and the man who takes to morphia when the share market goes against him.

Furthermore, to be healthy minded. one must have enough religion or philosophy to provide a scale of values in the unlimited alternatives of life. Man can only find permanent contentment by living on a plane that is in some degree higher than that of the instinct-driven animal. Unless his choice is inspired by some purpose other than immediate gratification, he must ultimately sink to the level of the creature whose well-being is entirely conditioned by his environment. It would be vain to suppose that this is not a very usual destiny. Every doctor of experience would agree that an appreciable proportion of his most disheartening cases are people who have no object in life, whose experiences are sterile, whose memories have no significance, whose condition can only be improved by a transitory stimulus from without. Some, no doubt, suffer from a degree of mental defect, but many have sufficient intelligence if they would but apprehend the transforming effect on life of a purpose that emanates from permanent values.

---

* Being extracts from an address delivered at the annual general meeting of the Scottish Association for Mental Welfare at Glasgow on May 17th, 1935.

In his social adjustment the healthy minded man must feel a reasonable degree of confidence in his fellow-men. For every fully developed case of paranoia in our mental hospitals, there must be hundreds, if not thousands, who suffer from minor degrees of suspicion and mistrust; whose lives are blighted by this barrier to human harmony; and who poison the springs of social life for the community. Mental health also demands toleration. If we recall the familiar inferiority complex it is clear that many cases are partly, if not entirely, attributable to impatience and disparagement manifested chiefly by the adult towards the child. Above all, no one can be regarded as healthy minded who fails to accept his herd-status as one of reciprocal obligation. This adjustment of the individual to society has further implications. It should be an active participation in herd life. Neither a passive nor a compulsory participation fulfils the requirements. I would suggest that compassion, construction, or creation must enter into the relationship. The first is no doubt a derivative of the maternal instinct; the second sublimates masculine aggressiveness; the third is the expression of femininity.

The Question of Responsibility

If mental health is as complex as I suggest, how are we to attribute responsibility for its promotion and maintenance. Clearly we must begin with genetics. No community can raise its level of health, physical or mental, unless it breeds for health. This is axiomatic. Apart from sterilisation, which I am prepared to believe is of little ultimate importance, there is the much broader problem of certificates of fitness for marriage. This at once throws into relief the deplorable inadequacy of our knowledge; and when we realise how uncertain would be the voice of society in this matter, we must exercise tolerance towards the individuals who appear to us to procreate when they should refrain. Furthermore, it is to be remembered that the whole subject of transmissibility is pervaded with camouflage. Our genetic scientists are groping in a sphere where everyone has a vested interest to camouflage facts. The eugenic ideal is, on the surface, easy to promote, with all but the least educable of the community. But it is far from easy to secure that readiness to face reality, without which the data of genetics are subject to perpetual distortion. Therefore the responsibility for the dysgenic factor in the mental health of any community must be borne by the community at large, as well as by its scientific and professional advisers. The only exception is constituted by those individuals who are clearly ineducable in the matter of social responsibility, and for these society should accept the duty of rendering procreation impossible.

After genetics, we may consider the biogenic disturbances. This is a very wide group. It includes the exogenous poisons of which alcohol is still the chief representative. It comprises all the focal and systemic poisons from quinsy to syphilis. It covers all forms of organic deterioration, and most important of all, disequilibrium of the endocrine system, such as hypothyroidism.

The third and last group of mental disorders is the psychogenic. In many ways this is the most important. It must be borne in mind that these three groups can, and frequently do, overlap. Thus you may have a young man who is the victim of inherited defect, who suffers from a chronic sinusitis, and who develops well-marked neurasthenic symptoms on account of an unsympathetic foreman. The psychogenic disturbances of mental health are, in evolutionary precedence, the most recent. The genetic factor was clearly the earliest, being one that we share with animals. The biogenic we share with primitive man, but the psychogenic is the doubtful glory of civilised man. Civilisation implies an ever-increasing range of choice. Where primitive man has few alternatives and invariably makes his choice on grounds of immediate satisfaction, civilised man is incessantly faced with alternatives. He is called upon to exercise fine discrimination. If he is merely an instinct-driven animal he will sooner or later succumb to uncertainty. If, on the other hand, he is possessed of clear-cut values, he will discriminate with relative ease and maintain a consistent purpose in life. Man has to make his choice in the wide field of conceptual ideation that he derives from his cortical development, and in the equally wide field of material possibilities which he owes to his conquest of nature. Thus all extension of knowledge and all expansion of material development increase the pressure on his capacity of discrimination. In this development, civilisation presents two outstanding difficulties, machinery and monogamy. To each of these there has been, in recent years, one big-scale resistance.

Mechanisation and Monogamy

In so far as Mahatma Ghandi can be said to represent Swaraj, Indian nationalism has pitted itself against the mechanisation that characterises western civilisation. It is easy enough to recognise, if not to sympathise with, the object. Ghandi sees in western mechanisation a process that saps the citizen of individuality; that robs him of constructive or creative achievement; that renders him dependent on the machine and its owners; that concentrates on a few individuals the responsibility for intelligent thought and action. Ghandi sees the doubtful benefits to western man of a mechanised civilisation. His argument is that oriental man will be overcome by mechanisation once he accepts and admits it. So Ghandi very consistently does his bit of weaving every day. Sometimes he consistently travels on foot: at other times he inconsistently goes by train. Very inconsistently he reads and writes by means of lenses in a celluloid frame that Indian culture could never provide. Most inconsistently but most wisely he elected that his appendicitis should be treated by western surgery and western asepsis, rather than by the methods of the East. And the moral of this is that however injurious mechanisation may be to the mental health of man, it is a factor in reality to which man must adjust. That he has so far failed to adjust to it is probably admitted by all of us.

A strangely contrasted picture is presented to us by Soviet Russia. Its rulers are imposing mechanisation on a simple people with such enterprise and determination as command the wonder of the world. At the same time and by the same uncompromising methods, they have reduced monogamy to little more than a farce. By so doing they claim to have greatly limited the incidence of neuroses, and this claim it is not difficult to accept. But monogamy, more than all social phenomena, is to be judged, not by its influence on the mental health of the present generation, but by its effect on the character development of the next generation. It is open to us to anticipate that in another ten years, Russia may be faced with the problem of the antisocial or neurotic adult who was an unwanted or unprotected

Dr. H. Crichton-Miller in his address on the Stewardship of Mental Health said that the responsibility of doctors for mental health was small compared with that of teachers and clergy. Nevertheless they were expected to minister to the mind diseased, and no one who faced facts could feel that they had fulfilled this obligation creditably. [Full extracts from Dr. Crichton-Miller's address appear on page 1292.]

IRELAND

(FROM OUR OWN CORRESPONDENT)

MEDICAL ATTENDANCE ON THE CIVIC GUARD

FOR some time past there has been considerable discontent in the profession as to the conditions on which medical attendance is provided for the members of the Civic Guard, the police force of the Irish Free State. For some six or seven years after the force was organised medical attendants were appointed by the Chief Commissioners on similar conditions to those which existed in the time of the previous force—the Royal Irish Constabulary. In the ordinary course the post was offered to the dispensary doctor of the district in which a country station was situated, and the remuneration was on a capitation basis at the rate of two shillings per man per month. Some five or six years ago this system was changed. All medical men in the neighbourhood of the station where a vacancy for a medical attendant occurs are invited to apply for the post, stating their terms per visit. It is commonly believed that the applicant who is contented with the lowest fees is appointed, but this is denied by the authorities of the Guard, who state that other considerations are also weighed, such as proximity of residence and the wishes of the local members of the force. It is claimed that a considerable saving has been effected by the change of methods of appointment and of remuneration. On the other hand it is pointed out that this economy has been effected at the expense of health of the men of the force. When the medical attendant was paid on a capitation basis it was both his duty and his interest to exercise a general supervision over the station as regarded its sanitary condition and to pay attention to any matter which might injuriously affect the health of the men. At present he has no duty except to attend and give treatment to a sick man and he has no preventive or supervising duties. The claim that proximity of residence is given consideration by the authorities in making an appointment is not likely to be accepted, for in many cases medical men living ten, fifteen, or more miles away have been selected, to the exclusion of those living close to the station and in active practice in its immediate neighbourhood. In another respect also the medical care given to the Civic Guard has been criticised. The authorities give "general practitioner" treatment and nothing more except to a guard who is injured in the course of his duty. If a guard requires hospital treatment or special treatment of any kind he has to provide it at his own expense, or receive it as a charity patient in a hospital. It is true that the Government has made a substantial contribution to form the nucleus of a medical aid fund, but it repudiates any further responsibility. It would appear that it would be to the interest of the health of the men of the force if the Government were to take full responsibility for the care of their health as it does for that of men serving in the Army. The Civic Guard, like the Army, is a national force for the whole country under the control of the Government.

MEDICINE AND THE LAW

Claims against Deceased Practitioners

IT is often hard enough for a medical practitioner in his lifetime to repel a claim for damages founded on allegations of negligence in some instances scarcely remembered in the course of a busy practice. It will be harder still for his estate to repel such claims after his death when the chief witness for the defence cannot be called. The two principal medical defence societies, as their members are or will presently be informed, are taking steps to enlarge the scope of their protective activity so as to give the benefit of their help and advice to the executors and administrators of deceased members. The recent change in the law has been mentioned from time to time in these columns. Until last year there was a curious maxim, peculiar to the English common law and unknown in Scotland, to the effect that a personal action dies with the person. The maxim was mitigated by several complicated exceptions inserted by Parliament or by the law courts. Thus the Fatal Accidents Act of 1846 (better known as Lord Campbell's Act) enabled certain specified relations of a deceased person to claim certain limited kinds of damages against anyone whose negligence had caused the death. But it remained substantially true that the victims of a defendant's negligence might lose their remedy if the defendant died; their personal action would die with him. Last year the Law Reform (Miscellaneous Provisions) Act made an important change. Henceforth, when anyone dies, the causes of action subsisting against him or vested in him are to survive against his estate or for the benefit of his estate as the case may be. In other words it is now the law that an action for negligence against a surgeon or physician will not come to an end if the defendant dies. The executors of the surgeon or physician will have to fight the action at every conceivable disadvantage, since the man who best knew what had happened on the occasion of the alleged negligence will not be there to explain. Curiously enough, Parliament admitted that in certain cases this absence of the principal witness for the defence would work intolerable hardship. The Act is expressly excluded in claims for defamation and seduction, and in certain other circumstances, where the defendant is dead. Yet in allegations of professional negligence the death of the defendant is to leave the plaintiff free to launch or continue claims which only the defendant's evidence could properly rebut. Almost the only concession which will assist a dead defendant's executors is the statutory condition that either such claims must have been pending at the date of the defendant's death or else the cause of action must have arisen within six months before the defendant's death and proceedings must have been initiated within six months of the date on which his personal representatives assumed their duties.

There has scarcely been time as yet to judge how the Act will work. Already the courts have had to examine some of the problems it creates. But enough has probably been now said to convince all practitioners that the consequences of the change are an added argument for membership of one of the professional defence societies. The practitioner can hardly hope to escape the threat of litigation in his lifetime. It is to be feared that the new Act will encourage speculative claims against his estate after his death. These are best met with the expert help of societies which give special study to such contingencies.

Injuries to Inmate of Public Assistance Institution

On May 19th the North Somerset coroner investigated the death of a patient at the Wells Mental Institution, following injuries (which included 13 broken ribs) apparently incurred at the Frome Institution during attempts to restrain him. The deceased, a rag-sorter named Rowlands, was said to have shown signs of mental instability on May 8th and was sent to Wincanton Institution. It was stated at the inquest that, as there were only female nurses at that institution, he was removed from the Wincanton to the Frome Institution on May 12th. According to the night attendant at the latter place, Rowlands was restless, violent, and noisy all night, and had frequently to be put back into bed. The witness was assisted by two patients named Turner and Grise. He denied that he or Turner knelt on Rowlands or that a door was banged on him or that any impatience or temper was shown. The master of the Frome Institution had not been informed that Rowlands required restraint. Rowlands was sent next day to Wells, where he died. The certificate on which he was admitted at Wells said he was noisy and uncontrollable and required three men to keep him in bed. He was found to be bruised on the legs, arms, and chest, and an autopsy showed seven ribs broken on the right side and six broken on the left. The medical superintendent at the Wells Institution said that considerable violence must have been applied and that the ribs might have been broken by a knee being placed on his chest. It was stated that neither Turner nor Grise was capable of giving evidence. The jury returned an open verdict attributing death to hæmorrhage due to injuries received during the night at Frome.

Under the Public Assistance Order the master of an institution is obliged to notify the coroner within 48 hours of the death of a lunatic or alleged lunatic and he must also furnish a copy of a certificate by the medical officer stating, amongst other details, the apparent cause of death and any unusual circumstances attending the death, with a description of all injuries known at death or subsequently discovered. Thus, had the death occurred at Frome, there would presumably not have been wanting that measure of adequate investigation which public opinion demands. Under Section 160 of the Poor Law Act the Minister of Health has a general power to hold such inquiries as he may consider necessary or desirable. As regards inquests, coroners are vigilant to investigate any death occurring in a public institution where patients are treated among strangers in the absence of their friends and relations. It by no means follows that severe injuries to a patient are due to brutal and mistaken methods on the part of the staff or of his fellow-inmates; but it is obviously essential that cases of this kind should be thoroughly sifted by some independent authority.

West End Hospital for Nervous Diseases.—The accounts of this hospital show a balance of £1302. The X ray equipment, which had been condemned, has been renewed and as a generous gift towards this was received from the Bernhard Baron trustees the department has been named the Bernhard Baron X ray department. The in-patient hospital in Regent's Park received 582 patients, and 37,329 attendances were made by out-patients in Welbeck-street.

THE SERVICES

ROYAL NAVAL MEDICAL SERVICE

Surg. Lt. (D.). W. G. Finnie to *St. Angelo* for R.N. Hospital, Malta.

ROYAL NAVAL RESERVE

Proby. Surg. Sub-Lt. P. S. Luffman promoted to proby. Surg. Lt.

ROYAL NAVAL VOLUNTEER RESERVE

Surg. Lt.-Comdr. (D.). D. MacGregor to *Drake* for R.N.B.

ARMY MEDICAL SERVICES

Colonel W. P. MacArthur, D.S.O., director-general of Army Medical Services at the War Office, has been selected for appointment as commandant of the Royal Army Medical College, and promotion to major-general, from Sept. 26th next, in succession to Major-General R. B. Ainsworth, D.S.O., who retires on that date.

Colonel J. W. L. Scott, D.S.O., will then succeed Colonel MacArthur as deputy director-general, and will in turn be succeeded as assistant director-general by Brevet Colonel F. Casement, D.S.O., assistant director of pathology and hygiene in the Western Command.

ROYAL ARMY MEDICAL CORPS

The undermentioned Lts. (on prob.) are secd. under the provisions of Art. 213, Royal Warrant for Pay and Promotion, 1931: M. Kosloff, J. McN. Lockie, A. Gleave, J. L. Gordon, G. G. Robertson, A. M. Pugh, J. H. Taylor, D. Wright, and D. N. Keys.

SUPPLEMENTARY RESERVE OF OFFICERS

Lt. J. N. Heales to be Capt.

TERRITORIAL ARMY

Maj. E. Scott, D.S.O., to be Lt.-Col.

Lt. L. J. Beynon, from 19th Lond. R., to be Capt.

A. T. Halton and I. R. Jones to be Lts.

Supernumerary for service with the O.T.C.—Lts. T. H. Wilson, A. C. Frazer, and C. L. Heanley to be Capts.

TERRITORIAL ARMY RESERVE OF OFFICERS

Capt. G. M. Goodwille, from Active List, to be Capt.

ROYAL AIR FORCE

Group Capt. A. Grant to Headquarters, R.A.F., India, for duty as Principal Medical Officer, vice Wing Comdr. R. W. Ryan.

Wing Comdrs. W. G. L. Wambeek to Station Headquarters, Heliopolis, Egypt, for duty as Medical Officer; T. Montgomery, to Headquarters, Western Area, Andover, for duty as Principal Medical Officer, vice Wing Comdr. A. J. Brown, D.S.O.; P. T. Rutherford, O.B.E., to No. 6 Flying Training School, Netheravon, for duty as Medical Officer.

Wing Comdr. T. S. Rippon is placed on the retired list.

Wing Comdr. T. S. Rippon, whose retirement from the R.A.F. is now gazetted, took a considerable part in research work on the mental aptitude for aviation and the essential characteristics of successful and unsuccessful aviators. This was referred to in The Lancet of September, 1918, and largely influenced the official methods of selection for Commissions. He qualified in 1911 and was educated at Bristol and the London Hospital, and had just established practice in Canada when the war broke out. He saw considerable service abroad and has been president of the Central Medical Board, R.A.F.

Flight Lt. J. Magner to Marine Aircraft Experimental Establishment, Felixstowe.

Flying Officers posted to Medical Training Depôt, Halton, on May 7th, on appointment to Short Service Commissions: P. A. Cooper, L. E. A. Dearberg, R. C. H. Tripp, H. L. Willcox, A. R. C. Young; J. C. Blair to Station Headquarters, Amman.

Flying Offrs. promoted to rank of Flight Lt.: D. R. Crabb, V. D'Arcy Blackburn, H. Bannerman, and H. S. Barber.

RESERVE OF AIR FORCE OFFICERS

Flight Lt. R. J. I. Bell relinquishes his commission on completion of service.

INDIAN MEDICAL SERVICE

The appt. of Lt. (now Capt.) T. K. White is confirmed.

Lt.-Col. R. H. Lee retires.

GENERAL MEDICAL COUNCIL

PRESIDENT'S ADDRESS

THE 141st session of the Council was opened on May 28th, when Sir NORMAN WALKER, the president, read to the Council a loyal address to the King on the completion of his Silver Jubilee. In offering cordial and respectful congratulations upon the occasion to His Majesty the address ran:—

> Throughout the twenty-five years which your loyal subjects now commemorate with thanksgiving, the profession of medicine has enjoyed the special countenance and encouragement of Your Majesty, with the gracious support of Her Majesty the Queen and other members of the royal family. We beg most humbly to be permitted to record our dutiful sense of obligation and indebtedness for the royal patronage thus bestowed, and our hope and belief that it has proved a source of profound benefit to the science and art of medicine as well as to the whole people themselves, not only throughout the Empire but among men of goodwill in every land. We gladly and proudly recognise that Your Majesty's reign has been signalised by remarkable advances in the healing art, which have brought relief to the suffering and the promotion of better conditions of life among all classes of the community. New discovery since 1910 has provided medicine and surgery with new means of healing for diabetes, for certain widespread forms of anæmia and malnutrition, for crippled and defective children, for the wounded soldier and the injured workman, and for the mending of the maimed and the prevention and defeat of disease. Advance has also taken place in the science of physiology, which gives good hope for the better and fuller life of the normal man. In a single generation the "expectation of life" for all men has been extended some seven or eight years. Above all, Your Majesty's reign has been made famous by the enormous extension of facilities for bringing the blessing of health and recovery from sickness to millions of your subjects who formerly lacked such assistance in their time of need: this great fact is demonstrated beyond doubt by the medical service made available during the war, by the progress of the child welfare and school medical services, by the health insurance of sixteen million persons, by the reform of the poor-law medical service, and by the enormous expansion of the voluntary and municipal hospitals. In all these popular and practical changes we recognise not only the will of Parliament but the sympathetic and upholding hand of the King.

The address, signed by the President, by Sir George Newman, and Mr. Herbert Eason as respectively senior and junior treasurers, and Mr. Michael Heseltine, the registrar, concluded by expressing thanksgiving for His Majesty's continued health and reign and an earnest desire that there might be granted to him and to the Queen "many more happy, peaceful years with ever-widening opportunities for the display of their beneficent influence and encouragement at home and abroad."

Sir Norman Walker then referred to the deaths which had occurred since the last session of two members, Prof. Arthur Thomson and Sir Leslie Mackenzie. He recalled the active part taken by Prof. Thomson in everything concerned with medical education and to the firm views which he held as to the importance in the educational scheme of a thorough knowledge of anatomy. Of Sir Leslie Mackenzie he said: "Education interested him in every connexion, and before he began his medical studies he had won as a graduate in arts the Ferguson scholarship in philosophy, the blue ribbon of the four Scottish universities." Philosophy ran through all his subsequent work and made him a valuable member both of the Education and Executive Committees of the Council. The president welcomed as his successor as Crown nominee for Scotland, Dr. John Ritchie, M.O.H. for Dumfries, and he reminded the Council that Dr. William Bruce, the first direct representative for Scotland, was medical officer of health for the County of Ross.

Sir Norman Walker went on to congratulate Sir Holburt Waring who was for nearly 12 years a treasurer of the Council upon receiving a baronetcy, and Sir Walter Langdon-Brown, representative of the University of Cambridge, upon his knighthood. He further extended congratulations to Prof. Stopford, the representative on the council of the Victoria University of Manchester, and also the university, on the appointment of Prof. Stopford as vice-chancellor.

The president continued: The Executive Committee at their meeting in February decided that it was right that your president should offer to give evidence before the Select Committee of the House of Lords to whom the Bill for the Registration and Regulation of Osteopaths stood referred. I took the opportunity to expound the merits of our British system of one Register for qualified medical practitioners, and am hopeful that the system which has worked, and worked well, for nearly 80 years will be maintained.

You have in your hands the report of the Curriculum Committee appointed last June. Sir Richard Quain said in his presidential address on Nov. 22nd, 1892: "It is now recognised, and it is my hope that it will be more and more recognised every year, that the Council is doing all in its power to secure the higher education of the profession and to elevate and maintain its character in all that is essential in connexion with the welfare of the public, within the lines marked down for us by Parliament. . . In some other countries these duties devolve on Government officials: happily here they are placed in our own hands, and I am confident that we shall not fail to prove worthy of the trust thus reposed in us." The Curriculum Committee have worked very diligently, and the report has been considered and reconsidered again and again. In its present form it represents the combined wisdom of its members. It is not for me to go into any details; these will be dealt with by the chairman, Dr. Tidy, but it is proper that I should indicate from the chair what seems the best method of dealing with the report.

Another of my predecessors has said that "education is the primary occupation of the Council, and time must be provided for its consideration." It is always difficult to construct a time-table for the Council's sessions, but we have provisionally earmarked Thursday or Friday forenoon for the purpose. It is suggested that the discussion should follow the lines of a second reading debate on a motion that the report be received by the Council and circulated to the licensing bodies with a request for their comments and criticisms. Coöperation between the General Council of Medical Education and Registration of the United Kingdom and the licensing bodies is the root principle of the British method of medical education, and it will be advantageous if communications can be received from the bodies in time to be dealt with at the November session.

The Medical Register had added to it in 1934 1664 names, a number exceeded, sometimes considerably, in the years 1921 to 1927 inclusive. There were 898 deaths, and the number removed from the Register for other reasons, the great majority under the provisions of Section 14 of the 1858 Act, was

61; the 1935 Register, which includes the Colonial and Foreign lists, therefore contains 57,496 names. The figures showing the number of students registered by the Council in 1934 are: in England 1094, a decrease of 37 as compared with the number in 1933; in Scotland 724, an increase of 25; in Ireland 532, an increase of 75. The total 2350, which thus shows an increase of 63 over the total for the previous year, has only twice been exceeded, in the years 1919 and 1920, when the totals were 3420 and 2531. I recall our past experience that when trade is bad, entries of medical students go up, and vice versa. There are schools which are conscious of the fact that their equipment and staff are being severely strained, and that they must consider limitation of entry. But there is a general feeling of hope in the air to-day, and perhaps the severe limitations under consideration in some places may not be necessary. There will not, I feel sure, be any tendency to lower the standard of entry even if numbers do go down a little.

A report will be presented to you by the Finance Committee which shows that for the first time since 1929 the expenditure of the general and branch councils for the last year exceeded their income. The deficit, which amounted in round figures to £650, was primarily attributable to the expenditure of over £1300 unavoidably incurred by the English branch council on account of three contested elections of direct representatives. I am hopeful that before the necessity for further expenditure of this nature again arises, amendments of Section 8 of the Medical Act, 1886, which will simplify and cheapen the procedure, will have been secured by legislation. As regards our financial position generally, I think I may so far anticipate the statement to be made by the treasurers as to say that on a broad view of the results of the last quinquennium, we may regard with composure the deficit for the year 1934 if we set against it the surpluses, amounting in all to over £3500, realised in the other four years of that period.

At the conclusion of his address a vote of thanks to the President was proposed by Mr. G. H. Edington, and seconded by Dr. H. G. Dain. Dr. John Ritchie, the new Crown nominee, was introduced by Mr. Ernest Miles. Sir Robert Bolam was re-elected chairman of business.

After deliberation in camera, the President announced that the name of Ernest Wardman Willbourne had been restored to the Register. The Council then proceeded to the consideration of penal cases.

PANEL AND CONTRACT PRACTICE

A Californian Health Insurance System

THE citizens of California have long been noted for their independence of outlook, receptivity to new ideas, and readiness to adapt themselves to the changing conditions of modern life. Hence it is not surprising that California seems likely to be the first State of the American Union to adopt compulsory health insurance, which, incredible as it may appear to medical men in this country, is regarded by many American doctors as a step towards a system of socialised medicine of the Russian type. A health insurance Bill has recently been introduced into the State legislature, and since it is supported by the California Medical Association it is expected to become law. The Bill is the outcome of an investigation into sickness costs recently completed by a committee of the legislature, which produced results believed by the investigators to be representative of the conditions throughout California. Some 20,000 families were studied, of which 15 per cent. had annual family incomes of less than $500, 39 per cent. less than $1000, and 51 per cent. less than $1200. The investigators found that large numbers of the poorer classes do not receive the medical care they need, and that much of the care that is received is given at the cost of the attending doctors; no less than 70 per cent. of the total amount due for medical services to families with annual incomes below $3000 is not recovered by the doctors giving the services.

This result is the more remarkable since California has suffered less than most States from the economic depression. The survey indicated also that in 1933 one-third of the California doctors were earning net professional incomes of less than $2000, one-half less than $3000, and three-fourths less than $5000. Such being the earnings of a large proportion of the medical profession in a community in which the cost of living is higher than in this country, it is not surprising that many doctors are supporting the health insurance Bill; for State health insurance, whatever its defects may be, eliminates, so far as the insured population is concerned, such deplorable features of medical practice as unpaid services, bad debts, and costs of collection. The system set up by the Bill is on a compulsory and contributory basis, both employers and employees paying their shares of the cost of the system. The contributions will vary with the wages earned; the employees will pay 3·5 per cent. of their wages and the employers 1·5 per cent. Medical and dental treatment will be provided for the insured persons and their dependants; and as additional benefits, home nursing and institutional convalescent care may be given. No provision is made for cash benefits. The system presents features that illustrate the latest tendencies in European health insurance: separation of medical services from cash benefits, free choice of doctor from among the doctors undertaking insurance services, extension of medical treatment to the dependants of insured persons, and participation of the medical profession in the administration of the system, which will be controlled centrally by a commission of five members, two of whom must be doctors and three laymen.

A novel feature of the system, which, so far as we are aware, has no counterpart elsewhere, is that a doctor undertaking insurance practice must obtain a licence, renewable annually, from the Commission, for which a fee of $5 is paid, and must execute a bond for a substantial sum to guarantee the due performance of his duties. The Commission is to be given very wide powers, apparently to render it as far as possible free from political pressure. The Bill if it becomes law will furnish an interesting and distinctively American contribution to the problem of providing care for the poorer sections of the community; and doubtless it will in its practical working do much to reassure those doctors in other States of the Union in whose minds compulsory health insurance is associated with the Red Flag.

Medical Benefit in Scotland

From the sixth annual report of the Department of Health for Scotland we learn that in the year 1934 some 1,900,000 persons in Scotland were insured—

roughly the same number as in the county of London—in the proportion of two-thirds males to one-third females, or about 54 per cent. of the total male and 26 per cent. of the total female population. Medical benefit for insured persons cost about £1,000,000, of which £170,000 was spent on drugs and appliances. There has been a decline in the extent to which approved societies have utilised the services of regional medical officers for examining insured persons whose continued incapacity for work is considered doubtful. The peak year was 1932; in 1933 there was a reduction of over 8000, and a further similar reduction brings the figure down to 44,870. Recently, except in 1933, the references in respect of men have been fewer than in respect of women, and the return to the normal in 1934 is accounted for by the reduction in the number of references being greater for men than for women. The proportion of cases in which the R.M.O. agreed with the medical practitioner that the insured person was incapable of work was higher—by fully 2 per cent.—in 1934 than in the previous year. Some of the part-time practitioners who examine insured persons are specialists in various branches of medicine. Special blood examinations, fractional test-meals, and urea-concentration tests are available for the R.M.O. in making his decision in difficult cases. An important part of his work, which deserves not to be overlooked, is to give advice in carrying out national health insurance duties. The year 1934 has seen a general improvement in the relationship of the regional medical staff with the insurance practitioner.

The Cost of Drugs

An insurance committee in Lancashire recently had under consideration a report on the cost of drugs per head of the insured population for nine county boroughs. It appeared that the cost last year in pence was: Oldham, 45·9; Blackburn, 44·8; Barrow, 43·6; Preston, 43·3; Bury, 39·4; Burnley, 38·4; Blackpool, 35·0; Rochdale, 34·34; and Bolton, 34·0. The cost per head in London for 1934 was 37·01. The curious fact that in Oldham the cost is a third more than in Bolton doubtless has some good cause which it would be profitable to discover. It may be recalled that Manchester recently looked into the causes of the high cost of supplying drugs and appliances in that area.

Friendly Guidance

The clerk of the London Insurance Committee has issued another of what he calls his "written chats." He opens with an apology that on this occasion the letter is not accompanied by a cheque, expresses his "not entirely unselfish" pleasure at the prospect of the early withdrawal of the economy cuts, and then proceeds as follows:—

> There is, however, another very real reason for my writing to you now. As you know, if an insured person on the list of another local practitioner wants to transfer to you, he must, if he is unable to obtain the consent of his own practitioner, write to me for the consent of the Committee to his transferring at the end of the quarter. This consent is given in the form of a red printed slip (A1) attached to the medical card. I know that many insured persons have a disinclination to signing their names, but Part A1 definitely provides for and therefore requires the *signature* of the insured person himself, although in the past we have not insisted upon it any more than we insist upon a signature in Parts "A," "B," "C" or "D" of the medical card. A number of cases have occurred recently, however, in which it has been alleged that the insured person had no desire to change his doctor, but that someone else had engineered the transaction without his knowledge. For your own sake then, will you please, in future, insist that if a person wants to transfer to your list he shall himself sign the Part A1. For my part, it will be my unpleasant duty to reject any transfer acceptances of this kind which are not properly completed by the applicant as well as by the doctor. No one dislikes red tape more than I do, but this particular piece has been forced upon me, and any inconvenience which would arise as a result of it can be prevented if you and your medical colleagues will coöperate by insisting that Part A1 (the red printed slip) and, if possible, medical cards as well, are properly completed before you send them here.

A reference to information attached to medical cards regarding the allocation of insured persons who fail to select an insurance practitioner is followed by a concise statement of what may and should be prescribed by insurance doctors, written from the positive point of view. This should once and for all prevent such inquiries as "Am I permitted to prescribe cod-liver oil for patients other than those suffering from tuberculosis?" or "May I order vaccines for insured persons?" which we understand have actually been received recently. The clerk gives a gentle reminder to any practitioners who may have been remiss in returning medical records, and in a postscript he relents to the extent of indicating that if the recipient is entitled to receive a cheque in connexion with the final settlement for 1934 he will find it enclosed with the letter.

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDED MAY 18TH, 1935

Notifications.—The following cases of infectious disease were notified during the week: Small-pox, 0; scarlet fever, 1990; diphtheria, 1057; enteric fever, 17; acute pneumonia (primary or influenzal), 949; puerperal fever, 53; puerperal pyrexia, 96; cerebrospinal fever, 19; acute poliomyelitis, 9; acute polio-encephalitis, 1; encephalitis lethargica, 5; dysentery, 14; ophthalmia neonatorum, 84. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the London County Council on May 24th was 3161, [illegible] Scarlet fever, 957; diphtheria, 1274; me[illegible] cough, 388; puerperal fever, 27 mothe[illegible] phalitis lethargica, 269; poliomyelitis, 3. At St. Margaret's *Hospital there were 19 babies (plus 9 mothers) with* ophthalmia neonatorum.

Deaths.—In 121 great towns, including London, there was no death from small-pox, 1 (0) from enteric fever, 21 (0) from measles, 6 (0) from scarlet fever, 21 (4) from whooping-cough, 37 (3) from diphtheria, 30 (9) from diarrhœa and enteritis under two years, and 73 (5) from influenza. The figures in parentheses are those for London itself.

Diphtheria occasioned 5 deaths at Liverpool, 3 at Hull, 2 each at Leeds, Manchester, and Oldham. Six fatal cases of measles were reported from Wigan, 3 from Sunderland. *Deaths from* whooping-cough numbered 3 at *Middlesbrough and at* Stoke-on-Trent. Of the much diminished deaths [illegible] 6 were reported *from* Manchester, 5 from [illegible] Leeds, 3 each from Acton, Blackburn, [illegible] Birmingham.

The number of stillbirths notified during the week was 289 (corresponding to a rate of 40 per 1000 total births), including 51 in London.

WEST LONDON HOSPITAL.—The Silver Jubilee extensions to this hospital will be finished in a few months' time, when the institution will be equipped with up-to-date casualty, X ray (diagnostic), and pathological departments. About £20,000 is still required to cover the cost.

CORRESPONDENCE

STIMULANTS OF METABOLISM

To the Editor of THE LANCET

SIR,—In your last issue Prof. E. C. Dodds and Dr. J. D. Robertson comment on the statement by Sir William Willcox that dinitro-phenol and dinitro-o-cresol are poisons to the liver and kidney cells. I do not think that anyone has much experience of the post-mortem findings in humans poisoned by these drugs, but I performed the autopsy in one proved case of poisoning by dinitro-o-cresol and examined the liver microscopically in a second where "some slimming drug" had been taken. In both these women there was severe damage to the liver and in the first case to the kidney also. It is interesting that the fat in the liver shows a very high proportion of fatty acid so that it stains a bluish purple with nile blue sulphate. In the proved case, the cause of death was respiratory failure due to pressure on the medulla by the cerebellum in the foramen magnum owing to the severe œdema of the brain, the pressure cone being well marked. It is difficult to understand how this could be produced solely by over-stimulation of metabolism.

Donald Hunter (THE LANCET, 1933, ii., 995) recorded the results of treating over 500 fat women in the east end of London with diet alone. They lost an average of 20 lb. each in three months, and none complained of hunger during treatment. It would seem to a mere morbid anatomist that reduction of weight might be brought about more safely and cheaply by suitable diet than by the use of drugs which all admit may easily prove fatal if not administered with great care and controlled by frequent measurements of the basal metabolic rate, and whose sole indication would appear to be to allow self-indulgence without obesity. Has Prof. Dodds changed his opinions since he gave the opening address at the Middlesex Hospital medical school in 1933? (THE LANCET, 1933, ii., 1933).

I am, Sir, yours faithfully,
WILFRID D. NEWCOMB.

St. Mary's Hospital, W., May 24th.

To the Editor of THE LANCET

SIR,—I have read with interest Prof. Dodds and Dr. Robertson's letter referring to the use of dinitro-phenol and dinitro-o-cresol in the treatment of obesity. They state that "provided a careful watch is kept on the patient and the basal metabolic rate is measured frequently, there is no danger in their use." Can a careful watch be kept over obese patients who are reducing in their own homes? These constitute the vast majority of would-be-reducers. The physician is lucky if he sees them once a week. Moreover, the average doctor has not the means, nor the average patient the money, to pay for repeated B.M.R. tests. The penalty for failure to adjust the dosage correctly is a series of exceedingly uncomfortable symptoms, and graver effects have actually been recorded.

The writers of the letter "feel that the important point to be emphasised is that the real risk arises from indiscriminate use of the drug." Dinitro-o-cresol received a wide advertisement in March, 1934. Once a drug is on the market, often it jumps from the hands of the expert into the arms of the foolish. Its indiscriminate use cannot be prevented. This is particularly true of weight-reducing medicines in general, many stout people being willing to try any means of slimming which does not impose dietetic restriction.

The cure of obesity by correct dieting is safe and certain. Can the same be said after the administration of such drugs as dinitro-phenol and dinitro-o-cresol? Their action in raising a normal basal metabolism to an abnormal level may seem an ingenious way of increasing output over intake but it must be a highly unnatural one. The short-cut to slimness is usually fraught with perils. If, of course, all cases of obesity could be attached to a laboratory for repeated investigations, eliminating the untoward happenings which may occur, I should not have written this letter. Until then, however, I agree with Sir William Willcox that their use should be avoided in clinical practice.

I am, Sir, yours faithfully,
W. F. CHRISTIE.

Lancaster Gate-terrace, Hyde Park, May 26th.

A CASE OF CANNABIS INDICA INTOXICATION

To the Editor of THE LANCET

SIR,—In the issue of THE LANCET dated April 6th, page 811, a clinical note under this title appeared, written by Dr. E. T. Baker-Bates, assistant honorary physician to the Royal Southern Hospital, Liverpool. The circumstances of the case made a popular appeal. In particular an article appeared in the *Liverpool Echo* with sensational cross-headings based upon the story as told in the columns of THE LANCET.

This patient was seen by me on Sept. 28th, 1933. She was admitted to the Stanley Hospital, Liverpool, at my request, and detained there for not more than 24 hours, where Dr. Baker-Bates was then on the staff. The original investigation of the case was conducted by me, and at first the police in Liverpool held the view that the plant, the smoking of whose leaves had caused the intoxication, was not cannabis indica but mugwort, and I was subjected to some "leg-pulling" by the police until an examination by Prof. Walter Dilling proved my diagnosis correct. I read a note at the time to the Liverpool Twenty Club on the case—this is a club of medical men which discusses papers on medical and lay subjects, and its proceedings are influential on things medical in Liverpool. Dr. Baker-Bates was present at the meeting as a guest. Six weeks ago I read the same note to the Wallasey Medical Society.

After the publication of the account of the case by Dr. Baker-Bates in THE LANCET of April 6th, 1935, and the long comment on it in the *Liverpool Echo,* I received the following letter from the chief constable of the Liverpool City Police, Mr. A. K. Wilson: "I read the other evening in the *Liverpool Echo,* and subsequently in THE LANCET, an article purporting to emanate from Dr. E. T. Baker-Bates respecting a case of cannabis indica poisoning in Liverpool. As the only case the police of this city have on record is that of Miss ——, of ——, Liverpool, which occurred on Sept. 28th, 1933, and which you investigated, I should like to know if the reports in the *Liverpool Echo* and THE LANCET refer to your case, or whether another case has arisen which has not been brought to the notice of the police. I observe so striking a similarity between the article in THE LANCET and the article written in the *Police Journal* of July-September, 1934, by my assistant, Mr. H. Winstanley, that I am forced to the conclusion that the same case is referred to. I did not know that Dr. Baker-Bates took any part in your investigation, but perhaps you will let me know in your reply if he did so. With regard to the *Liverpool Echo* report, I think you will agree with me that it is definitely not in the public interest that a case of this nature should be reported in the popular press." The chief constable enclosed a copy of the article which appeared in the *Police Journal*, July-September, 1934, and the similarity of the facts as stated in that article with those given in the article in THE LANCET is striking.

In his communication to THE LANCET Dr. Baker-Bates made no mention of my connexion with the case further than that "she was taken to a doctor and the history explained; he recorded, &c."; nor has he ever applied to me for any information; but the symptoms which he mentions are stated in almost the same words as those which appear in Mr. Winstanley's article in the *Police Journal*.

I am placed in a peculiar position on which there has already been comment, for when the case actually occurred it created some sensation and there is no doubt that the Liverpool police, the members of the Twenty Club, the Wallasey Medical Society, and many members of the profession in Liverpool all understood that the case had originally come under my treatment. I wrote to Dr. Baker-Bates on April 10th last, sending him a copy of the letter from the chief constable of Liverpool and asking for the source from which he obtained the notes which his article in THE LANCET stated to be "recorded" by a doctor. He telephoned in reply, and was told that I preferred not to discuss the matter on the telephone. Since then I have heard nothing from Dr. Baker-Bates.

I am, Sir, yours faithfully,
W. A. J. FLEMING.

Wallasey, May 18th.

ADMINISTRATION OF CARBON TETRACHLORIDE FOR HOOKWORM

To the Editor of THE LANCET

SIR,—Having read from time to time of deaths caused by carbon tetrachloride, I have come to think that the method of administration may have some influence. I have treated many hundreds of cases of ankylostomiasis on various estates and give carbon tetrachloride to all the labour force as a routine measure every six months. Only in very exceptional cases, however (perhaps one in a thousand), has there been any complaint even of discomfort, when the man treated has complained that the medicine "made him feel a little drunk." In the great majority of cases there has been no apparent discomfort, and the patient has gone about his daily duty immediately after receiving his dose.

Adults receive Tetraform 3 c.cm. in ol. ricini 15 c.cm., or approximately tetraform ♏50 in castor oil ½ oz. The mixture has to be thoroughly shaken, for the tetraform is heavier than the oil. Occasionally, in cases of Europeans "who cannot take castor oil," Internol (paraffin. liquidum B.D.H.) is substituted for the castor oil; it seems equally effective and the taste of the mixture is even pleasant, one patient likening it to raspberry flavouring.

Thus diluted, carbon tetrachloride seems to have no ill-effect, so I am passing on the information to those who give it otherwise. No purgative is needed after its use, and this is an advantage for all concerned.

I am, Sir, yours faithfully,
A. S. TUXFORD, L.M.S., H.K.

Lahad Datu, North Borneo, Jan. 26th.

PSITTACOSIS AND VIRUS INFECTION

To the Editor of THE LANCET

SIR,—The observations on so-called psittacosis recorded in your last issue may be interpreted otherwise than in your leading article. From my work on infections in general I infer that this condition belongs to what I term "infections from within"—i.e., infections caused by the mutation forms of the *Bacillus coli communis* in the large intestine, some of which develop (the earliest to mutate) into coccoid, sub-coccoid, and ultra-microscopic forms at certain periods in man and animals alike. The development into sub-phases is determined by the resistance of the host, a phenomenon which results from the establishment of immunity. It so happens that the changes occurring in the bacterial flora in the excreta in man are paralleled by those which take place in seed-eating birds, particularly in those recently brought into captivity. In the winter 1929–1930 the *Bacillus fæcalis alkaligenes* was terminating a cycle, the result being its development into sub-phases, some of which were responsible for one of the forms of influenza prevalent at that time. As the hosts had not had time to establish an immunity against these sub-phases, being newcomers, infections not only arose spontaneously in man and certain animals, but also they were intercommunicable. Recently the *Streptococcus fæcalis* has been undergoing a similar change, and the new cases of so-called "psittacosis" arising are being caused, both by the parent micro-organism and by the sub-forms into which the immunity of the hosts is making it develop.

As no infections occur naturally through the intraperitoneal route, it is not justifiable to draw inferences from what happens when this route is employed to cause an infection artificially; indeed, no reliance is to be placed upon experiments conducted on animals with micro-organisms which are pathogenic to man. Extracts of organs damaged by drugs and passed through filters may occasion manifestations of disease when injected intraperitoneally and intracerebrally, indistinguishable from those met with in infections; from which the inference may be drawn that all invaders, be they micro-organisms, physical agents, or chemical poisons, act fundamentally in the same way in producing disease.

The whole subject of disease wants overhauling, and no part of it more than the most recent one which deals with ultra-microscopic viruses. Because all of them are sub-phases of certain well-known bacilli and many when not formed naturally, may be readily generated by the actual process of filtration. If correlation were practised in place of differentiation, I am convinced so-called "psittacosis" would be found to be a form of influenza and not a specific infection. Influenza is always with us and filtrable viruses only play a part in its production when their parent bacilli are completing a cycle. And not all the bacilli responsible have reached the stage where they are capable of developing into sub-phases. The micro-organisms which have been extant sufficiently long to form sub-phases are Friedländer's bacillus, the *Bacillus fæcalis alkaligenes*, *B. proteus* X 19, and a certain streptothrix, and some of those formed by the last two have received the names of "rickettsia" and "pasteurellæ," respectively. Some of those formed by the *Bacillus fæcalis alkaligenes* have been classed amongst the pfeifferellæ and those formed by Friedländer's bacillus and its offspring the *Streptococcus fæcalis* have so far not been named, despite the fact that the infections caused by them are those best known. Many sub-phases are of e same nature as those which are called "toxines" hen liberated by the clostridia, thus explaining why ese micro-organisms do not form spores when they use disease. They cause disease only when the sistance of the host breaks them down, or subjects em to dehydration, whereas spore formation is an hibition of hydration.

I am, Sir, yours faithfully,

Wimpole-street, W., May 28th. J. E. R. McDONAGH.

ERGOMETRINE

To the Editor of THE LANCET

SIR,—It is unfortunately necessary to comment ery briefly on the letter by M. S. Karasch and . R. Legault, which you published under the heading Ergotocin" in THE LANCET of May 25th (p. 1243). or the guidance of those who might otherwise be isled, I wish simply to state that all the available vidence indicates that the substance isolated by arasch and Legault, to which they have transferred he trade name "ergotocin," is identical with the lkaloid ergometrine, which Moir and I originally escribed in the *British Medical Journal* of March 16th. oth my own subsequent preparations, in quantities ermitting adequate recrystallisation, and those of everal British manufacturers which I have examined, ossess all the properties mentioned by Karasch and egault, and the uncritical suggestion that "ergo-ocin" may be chemically different from ergometrine and clinically more potent may be dismissed without hesitation.

I am, Sir, yours faithfully,

H. W. DUDLEY.

National Institute for Medical Research, Hampstead N.W., May 25th.

TREATMENT OF SCABIES

To the Editor of THE LANCET

SIR,—Scabies occurs mostly in those seeking free hospital treatment where expense is a matter of importance. Sulphur ointment is cheap and is reasonably efficient, and will cure scabies in a few days. This is the justification for sulphur treatment in spite of the objections indicated by Dr. Fraser. In private practice more elegant and expensive preparations as Bayer's Mitigal (dimethyldiphenylene-disulphide) or benzylbenzoate (according to Haxthausen's prescription) are employed and are more efficient than sulphur. Pesticides such as those employed for destroying beetles are likely to be dangerous, since they may be absorbed and the whole skin of a patient suffering from scabies requires treatment, not only his hands and arms. Not sufficient is known of the possible toxic effects of carboxide, ortho-dichlorbenzene, and such pesticides to allow of their being used on human skins, but Dr. Fraser's letter suggests a useful line of research.

I am, Sir, yours faithfully,

Leeds, May 25th. JOHN T. INGRAM.

OBITUARY

THOMAS CUNNINGHAM PENFOLD, M.B., C.M. Edin.

THE death occurred in a Newcastle nursing-home on May 13th of Dr. Thomas Cunningham Penfold, medical officer of health to the Chester-le-Street rural district council. He was a very capable public servant and rightly won the appreciation of the community for which he worked.

Dr. Penfold was born in 1872, the son of Mr. J. B. Penfold, of Brampton, Cumberland, and received his medical education at the University of Edinburgh and King's College, London. He graduated as M.B., C.M. Edin. in 1894, and took the English double qualification several years later, while in 1908 he obtained the diploma of D.P.H. R.C.S.I. For a few years he was in general practice, part of that time being associated with his brother, Dr. W. J. Penfold, now the director of the Baker Research Institute at Melbourne; but in 1901, having decided to enter the public health service, he was appointed medical officer of health for Hexham rural district council. In 1914 he was appointed to the same post with the Bishop Auckland rural district council, and 10 years later, following a redistribution of the public duties, he became medical officer of health to Chester-le-Street. The period over which Dr. Penfold's public work extended will be seen to have been an important one in sanitary administration. He commenced his official duties with the present century, and he was therefore engaged in the promotion of all the changes in public sanitation, in State education as bearing on health, and in the formulation of regulations for the promotion of child welfare which were making their appearance before the outbreak of war, and which during the last 15 years have manifested general activity and, in some directions, remarkable progress. As was natural, having regard to the county in which his duties lay, he had the plight of the mining population always present to his mind, and wherever possible he assisted the miners in their profound difficulties. The slum clearance scheme set in motion by his rural authority is a large undertaking which was initiated with his counsel, and the help which he rendered in this direction will not be forgotten on its completion.

Dr. Penfold married Miss Isa Johnstone, of Brampton, and leaves a widow and three daughters.

DR. ABRAHAM GROVES.—News of the death of Dr. Abraham Groves, of Fergus, Ontario, has reached us this week. He was 88 years of age, and only last year recorded his life work in a book entitled, "All in the Day's Work," which was recently reviewed in these columns. His autobiography showed him to have been throughout more than 60 years of active practice an original and capable surgeon, while he was the first man in Canada to make an abdominal section for the relief of appendicitis. His early operating feats, as recorded by himself, were marked by ingenuity and followed, in some cases, with unusual success. He was for many years medical superintendent of the Royal Alexandra Hospital, Fergus, which has been renamed the Groves Memorial Hospital in his honour, and he thoroughly deserved the public recognition.

DR. JOHN PRATT, who was drowned on May 26th when a rowing boat capsized off the Cumberland coast, was medical officer of health for the Millom rural district council and superintendent of the Millom and Bootle infectious diseases hospitals. He was educated at Queen's College, Cork and Dublin, qualifying in 1904. He served as a temporary surgeon lieutenant in the Navy from November, 1914, and was awarded the Distinguished Service Cross in the following year. He had recently recovered from pneumonia.

PARLIAMENTARY INTELLIGENCE

NOTES ON CURRENT TOPICS

National Health Insurance Bill

ON May 23rd the National Health Insurance and Contributory Pensions Bill was introduced in the House of Commons and read a first time. The principal objects of the Bill are:

(1) To secure that persons who have been contributing to the interlocked schemes of National Health Insurance and Contributory Pensions for a sufficiently long period shall not forfeit their pensions rights or all their health insurance rights if they become unemployed and if the continued absence of contributions is due only to the fact that they are unable to obtain employment; and

(2) to provide that insured persons who are covered for sickness, disablement, and maternity benefits under the Health Insurance Scheme shall not suffer any reduction or suspension of those benefits by reason of arrears of contributions due to unemployment.

The cost of medical benefit and additional treatment benefits of unemployed insured persons will fall equally on the funds of approved societies and on the National Exchequer. It is proposed to set up a new Unemployment Arrears Fund contributed to equally by a levy on the contributions of members of approved societies and by an annual Exchequer grant. The amount of the levy will be such that when added to the equivalent Exchequer grant the sum will enable a grant to be made to each approved society at the rate of threepence halfpenny each week of proved unemployment of its members. In effect the Fund will spread over all the societies the burden of loss of contributions due to unemployment, each society contributing according to the volume of employment, and each receiving a grant in proportion to the amount of unemployment among its members.

The amount required for this purpose is estimated at nearly £1,500,000 a year. A Supplementary Estimate will not be necessary for the current financial year as the Bill provides that any disposable surpluses of the Navy, Army, and Air Force Insurance Fund not required for maintaining the additional prescribed additional benefits are to be paid into the Arrears Fund. At the valuation at the end of 1932 the available surplus was £701,000, and with the accrued interest this ought to be sufficient to provide the Exchequer grant for the first year. Under Clause 11 of the Bill arrears due to unemployment, which under the existing law are excused only to the extent of one-half will be excused in full from July 2nd, 1934. The effect of this concession is that any person who remains unemployed throughout a free insurance period will suffer no reduction of benefits during that period by reason of unemployment. It will also prevent any reduction in the benefits of the very large number of persons who, although in fairly regular employment, have varying periods of unemployment in the course of a contribution year. The increased cost involved in the complete excusal of arrears due to unemployment will also be met out of the Arrears Fund.

Water-supplies Inquiry

In the House of Commons on Monday, May 27th, Mr. ATTLEE asked the Minister of Health whether he could state the extent of the proposed inquiry by a Select Committee into water resources and supplies, and what powers it was proposed to give to the committee.—Sir HILTON YOUNG replied that the law relating to water-supplies required amendment in various particulars and proposals for this purpose had been made from time to time, including proposals in three reports of the Water Advisory Committee of his Department. It was considered that the most appropriate method of investigating the amendments desirable was by a Joint Committee of both Houses of Parliament, who could hear the various interests concerned. The Committee would, of course, be at liberty to investigate other aspects of the matter which they considered relevant to this purpose. It was proposed that the Committee should have the usual powers: to hear evidence and to make recommendations.—Sir F. FREMANTLE asked whether it would be within the purview of this Committee to consider the question of drains and sewage.—Sir HILTON YOUNG said that the *specific purpose* of the inquiry was to consider the water-supply, but his hon. friend would know that one could *not* consider that question without giving *some consideration* to the question of sewage.

Indian Civil Servants and Medical Attendance

In the House of Commons on May 28th, when the Government of India Bill was further considered on report, Mr. BUTLER (Under-Secretary for India) moved an amendment providing that the rights of all persons appointed to a civil service post by the Secretary of State in regard to medical attendance should be prescribed by rules made by the Secretary of State. He said that the Secretary of State had considered with great sympathy certain representations which had been made to him during the Committee stage of the Bill and he had decided that there was a case for adding the general rights in regard to medical attendance of civil servants to the questions on which the Secretary of State would make rules. This was a matter to which members of the civil service attached great importance. They had at present certain rights entitling them to medical treatment for themselves and in certain cases for their wives and families. The availability, for example, of a British medical officer in a station where there was a substantial body of civilians was a right to which they attached great importance and in view of the conditions of service in India and the special problems which arose in regard to medical attendance there he thought that the House would regard it as legitimate that this amendment should be made to the Bill.

The amendment was agreed to.

In the House of Lords on Wednesday, May 22nd, the West Riding of Yorkshire Mental Hospitals Board (Superannuation) Bill was read the third time. The Bill was introduced in the House of Commons on the same day and read a first time.

HOUSE OF COMMONS

WEDNESDAY, MAY 22ND

Ex-Servicemen in Edenhall Hospital

Mr. GUY asked the Minister of Pensions how many ex-Service men were undergoing treatment in Edenhall Hospital, and how many of these were in receipt of treatment allowances.—Major TRYON replied: There were 82 men undergoing treatment in Edenhall Hospital on May 20th. In 63 of these cases the men are in receipt of treatment allowances or continue to receive remuneration in excess of the treatment allowances which would otherwise be payable, and 15 are receiving allowances at pension rates. Of the remaining 4 cases 2 are at present under consideration.

Vivisection Certificates

Mr. GROVES asked the Home Secretary on what grounds a certificate for vivisection was issued, in view of the ambiguity of the wording of the licences and the wide powers conferred by various classes of certificates; and what steps, if any, were being taken to ensure that licences were not issued to persons merely interested for commercial ends.—Sir JOHN GILMOUR replied: Certificates given under the provisos to Section 3 of the Cruelty to Animals Act, 1876, dispensing with some of the conditions laid down in the earlier part of the section are given by e scientific authorities named in Section 11 of the Act, d not by the Home Office. A copy of any certificate ven must be forwarded to the Secretary of State and es not come into operation until one week after a copy s been so forwarded. The power of the Secretary of ate is confined to disallowing or suspending any certi- ate given under the Act.

Mr. GROVES asked the Home Secretary which establish- ents or individuals held licences for vivisection and did t fall into the category of either public or private mpanies.—Sir JOHN GILMOUR replied: Licences to rform experiments on living animals under the Cruelty Animals Act, 1876, are in all cases granted to indi- duals, and not to establishments or public or private mpanies.

THURSDAY, MAY 23RD

Medical Referees and Nystagmus Cases

Mr. TINKER asked the Home Secretary if he was aware the feeling amongst the workmen suffering from nystag- us against there being only one medical referee to ecide on cases sent before him, and if he would consider e advisability of making two medical referees in place one to certify the condition of the workman.—Sir OHN GILMOUR replied: The hon. Member's suggestion ould involve an important departure from the present rovisions as to medical certification which could not be dopted without full inquiry. The whole position in gard to this disease is under consideration.

Poisons and Pharmacy Act, 1933

Mr. HALL-CAINE asked the Home Secretary what rogress had been made with the drawing up of a new st of poisons under the Poisons and Pharmacy Act of 933: and by what date it was anticipated this new list ould be available.—Sir JOHN GILMOUR replied: I am formed that the Poisons Board has prepared the Poisons ist and is about to submit it to me, together with its ecommendations in regard to the rules to be made under he Act. It is hoped that the proposals of the Board ill be available to Members before the Whitsun recess.

Protection of Civilians from Gas Attack

Mr. MANDER asked the Home Secretary if he would ive particulars of the work to be undertaken by the egion of Frontiersmen in connexion with the protection f the civil population during gas attacks; and whether his included gas-mask drill, compulsory or otherwise.— Sir J. GILMOUR replied: I understand that the Legion f Frontiersmen, like some other voluntary organisations, s in touch with the Order of St. John and the British Red Cross Society with a view to assisting in the measures o be organised by those bodies for the alleviation of the onsequences of air attack. I have informed the Legion hat in my opinion assistance of this nature would be work of national importance. No specific duties have been allotted to this body at present, and any drill which may have been undertaken has been arranged voluntarily.

Flooding in Palestine; Fear of Malaria Epidemic

Mr. LECKIE asked the Secretary of State for the Colonies whether he was aware that on May 1st last the Sea of Galilee overflowed its banks and flooded the cellars of some of the houses in Tiberias, as well as the low-lying ground; that, owing to the formation of stagnant pools, there was fear of an epidemic of malaria; and whether he would take steps to insist that the sluices in the River Jordan should be kept open to prevent the raising of the lake in future above its normal level.—Sir PHILIP CUNLIFFE-LISTER replied: I have no information regarding the situation referred to in the hon. Member's question, but I have asked the High Commissioner for Palestine for a report.

Sewage Purification on the Tweed

Captain RAMSAY asked the Secretary of State for Scotland whether he was aware that at times when the water level of the upper reaches of the River Tweed was low there was serious pollution of the river through sewage and trade effluents, and that this state of affairs was likely to become much more marked by the present scheme to impound a substantial quantity of the head water for the Edinburgh supply; and what action he proposed to take.—The Lord ADVOCATE replied: With regard to the first part of the question my right hon. friend is aware that there is considerable pollution of the Tweed at certain points by sewage and trade effluents. With regard to the second and third parts, the proposals of the Edinburgh Corporation are contained in a Draft Provisional Order which has been lodged by the corporation and is being considered in accordance with the Private Legislation Procedure (Scotland) Acts, 1929 and 1933. In the circumstances my right hon. friend regrets that he can make no comment on the latter at present.

MONDAY, MAY 27TH

Births in England and Wales

Mr. GEORGE GRIFFITHS asked the Minister of Health the number of births in England and Wales for the years 1932, 1933, and 1934.—Sir HILTON YOUNG replied: The following is the information asked for:—

England and Wales: years.	Live births.	Stillbirths.	Total live and stillbirths.
1932	613,972	26,471	640,443
1933	580,413	25,084	605,497
1934 (provisional)	597,642	25,209	622,851

Maternal Mortality: Suggested Royal Commission

Mr. GRAHAM WHITE asked the Prime Minister if he would consider the advisability of appointing a Royal Commission to conduct a comprehensive inquiry into the causes of maternal mortality and make recommendations in regard thereto.—Mr. MACDONALD replied: No sir; I am not at present satisfied that an inquiry into the subject by a Royal Commission would be of advantage. I would refer the hon. Member to the answer given by the Minister of Health on March 28th (THE LANCET, April 6th, p. 838). The hon. Member will see that special inquiries are in progress in those areas where the incidence of maternal mortality is, or has been, most marked, and that when those inquiries are completed, my right hon. friend proposes to lay a White Paper on the subject before the House.

Infant's Death after Vaccination

Mr. GROVES asked the Minister of Health whether he was aware that Margaret Jane Pinnock, of Staines Road, Laleham, a one-month old baby, died from vaccination performed when the infant was five days old in order to enter an adoption home; and whether he would communicate with the societies that arrange for the adoption of children and remind them of the advice given in the last Report of the chief medical officer of the Ministry, to the effect that the authorities of such institutions should abolish their vaccination regulations.—Sir HILTON YOUNG replied: I am aware of the case referred to in the first part of the question. As regards the second part, I do not find that the last report of the chief medical officer of my Department advised that the authorities of institutions should abolish their vaccination regulations. The passage in the report to which the hon. Member appears to refer is not relevant to this case as it relates to the vaccination of adolescents and children of school age who have not previously been vaccinated.

Milk for School-children

Sir PERCY HURD asked the Minister of Health whether he was taking any action in respect of the refusal of certain county council medical officers to sanction the supply to schools of other than pasteurised milk; and whether his Ministry held it to be within the competence of medical officers to exercise their discretion in a manner contrary to instructions from their councils.—Sir HILTON YOUNG replied: The answer to the first part of the question is in the negative. As regards the second part of the question, I am advised that under the arrangements made by the Milk Marketing Board for the supply of milk at reduced rates, the approval of the source and quality of the supply is a matter for the professional discretion of the Medical Officer of Health.

PARLIAMENTARY INTELLIGENCE

NOTES ON CURRENT TOPICS

National Health Insurance Bill

On May 23rd the National Health Insurance and Contributory Pensions Bill was introduced in the House of Commons and read a first time. The principal objects of the Bill are:

(1) To secure that persons who have been contributing to the interlocked schemes of National Health Insurance and Contributory Pensions for a sufficiently long period shall not forfeit their pensions rights or all their health insurance rights if they become unemployed and if the continued absence of contributions is due only to the fact that they are unable to obtain employment; and

(2) to provide that insured persons who are covered for sickness, disablement, and maternity benefits under the Health Insurance Scheme shall not suffer any reduction or suspension of those benefits by reason of arrears of contributions due to unemployment.

The cost of medical benefit and additional treatment benefits of unemployed insured persons will fall equally on the funds of approved societies and on the National Exchequer. It is proposed to set up a new Unemployment Arrears Fund contributed to equally by a levy on the contributions of members of approved societies and by an annual Exchequer grant. The amount of the levy will be such that when added to the equivalent Exchequer grant the sum will enable a grant to be made to each approved society at the rate of threepence halfpenny each week of proved unemployment of its members. In effect the Fund will spread over all the societies the burden of loss of contributions due to unemployment, each society contributing according to the volume of employment, and each receiving a grant in proportion to the amount of unemployment among its members.

The amount required for this purpose is estimated at nearly £1,500,000 a year. A Supplementary Estimate will not be necessary for the current financial year as the Bill provides that any disposable surpluses of the Navy, Army, and Air Force Insurance Fund not required for maintaining the additional prescribed additional benefits are to be paid into the Arrears Fund. At the valuation at the end of 1932 the available surplus was £701,000, and with the accrued interest this ought to be sufficient to provide the Exchequer grant for the first year. Under Clause 11 of the Bill arrears due to unemployment, which under the existing law are excused only to the extent of one-half will be excused in full from July 2nd, 1934. The effect of this concession is that any person who remains unemployed throughout a free insurance period will suffer no reduction of benefits during that period by reason of unemployment. It will also prevent any reduction in the benefits of the very large number of persons who, although in fairly regular employment, have varying periods of unemployment in the course of a contribution year. The increased cost involved in the complete excusal of arrears due to unemployment will also be met out of the Arrears Fund.

Water-supplies Inquiry

In the House of Commons on Monday, May 27th, Mr. Attlee asked the Minister of Health whether he could state the extent of the proposed inquiry by a Select Committee into water resources and supplies, and what powers it was proposed to give to the committee.—Sir Hilton Young replied that the law relating to water-supplies required amendment in various particulars and proposals for this purpose had been made from time to time, including proposals in three reports of the Water Advisory Committee of his Department. It was considered that the most appropriate method of investigating the amendments desirable was by a Joint Committee of both Houses of Parliament, who could hear the various interests concerned. The Committee would, of course, be at liberty to investigate other aspects of the matter which they considered relevant to this purpose. It was proposed that the Committee should have the usual powers: to hear evidence and to make recommendations.—Sir F. Fremantle asked whether it would be within the purview of this Committee to consider the question of drains and sewage.—Sir Hilton Young said that the specific purpose of the inquiry was to consider the water-supply, but his hon. friend would know that one could not consider that question without giving some consideration to the question of sewage.

Indian Civil Servants and Medical Attendance

In the House of Commons on May 28th, when the Government of India Bill was further considered on report, Mr. Butler (Under-Secretary for India) moved an amendment providing that the rights of all persons appointed to a civil service post by the Secretary of State in regard to medical attendance should be prescribed by rules made by the Secretary of State. He said that the Secretary of State had considered with great sympathy certain representations which had been made to him during the Committee stage of the Bill and he had decided that there was a case for adding the general rights in regard to medical attendance of civil servants to the questions on which the Secretary of State would make rules. This was a matter to which members of the civil service attached great importance. They had at present certain rights entitling them to medical treatment for themselves and in certain cases for their wives and families. The availability, for example, of a British medical officer in a station where there was a substantial body of civilians was a right to which they attached great importance and in view of the conditions of service in India and the special problems which arose in regard to medical attendance there he thought that the House would regard it as legitimate that this amendment should be made to the Bill.

The amendment was agreed to.

In the House of Lords on Wednesday, May 22nd, the West Riding of Yorkshire Mental Hospitals Board (Superannuation) Bill was read the third time. The Bill was introduced in the House of Commons on the same day and read a first time.

HOUSE OF COMMONS

WEDNESDAY, MAY 22ND

Ex-Servicemen in Edenhall Hospital

Mr. Guy asked the Minister of Pensions how many ex-Service men were undergoing treatment in Edenhall Hospital, and how many of these were in receipt of treatment allowances.—Major Tryon replied: There were 82 men undergoing treatment in Edenhall Hospital on May 20th. In 63 of these cases the men are in receipt of treatment allowances or continue to receive remuneration in excess of the treatment allowances which would otherwise be payable, and 15 are receiving allowances at pension rates. Of the remaining 4 cases 2 are at present under consideration.

Vivisection Certificates

Mr. Groves asked the Home Secretary on what grounds a certificate for vivisection was issued, in view of the ambiguity of the wording of the licences and the wide powers conferred by various classes of certificates; and what steps, if any, were being taken to ensure that licences were not issued to persons merely interested for commercial ends.—Sir John Gilmour replied: Certificates given under the provisos to Section 3 of the Cruelty to Animals Act, 1876, dispensing with some of the conditions laid down in the earlier part of the section are given by pose. The sum includes the Bank's usual annual scription to the King's Fund, and certain annual scriptions which the Bank has previously made direct certain London hospitals. The balance is to be dis- buted by the Fund in response to such appeals from ndon hospitals as the Bank may receive and forward the Fund for consideration. The hospitals to be isted under the latter head, and the allocation among h hospitals, will be determined by the Fund at its eretion.

"It is satisfactory to know that the amount thus rusted to the King's Fund represents an increase upon average annual total sum hitherto dispensed by the nk in direct donations. These grants will be decided he autumn, just before our ordinary distribution. They l be quite distinct from the ordinary grants, and will ch the selected hospitals as donations from the Bank England, per King Edward's Hospital Fund. I should e, in your name and in mine, to express our appreciation the action of the Bank of England, and the pleasure it l give us to use on their behalf all our knowledge of circumstances of the various hospitals."

His Royal Highness then recorded the loss by ath of prominent members of the council since last meeting, making special reference to Lord merleyton, the senior honorary secretary, Mr. hitley, the chairman of the Parliamentary Committee the council, and Sir John Rose Bradford, chairman the out-patients' arrangements committee, adding at he had appointed Lord Macmillan in place of . Whitley, and Dr. Morley Fletcher in place of John Rose Bradford.

ACCOUNTS FOR 1934

ir Edward Peacock, hon. treasurer of the Fund, in moving adoption of the accounts, said that at the distribution December there was still a small deficit, but this was vered before the end of the year, though with a margin only £426. The total amount distributed was again 20,000. Annual subscriptions were £200 more than 1933 and donations £1,600 more. Legacies amounted £77,000. During the past seven years the lowest ure for legacies had been £58,000, and the average had en £70,000. There was no doubt that the King's Fund, th its annual grants to 200 hospitals and convalescent mes, made a strong appeal to testators who wished to leave legacies or residues to charity, but had no particular institution in their minds. But they would be glad to see a larger proportion of the increased distribution provided for by annual subscriptions. He would like to refer to the advantages, both to subscribers and to the Fund, from the use of seven-year agreements, which enabled income tax and surtax to be saved. Last year the Fund received 67 annual subscriptions under agreements of that kind, ranging from £1 1*s.* to £4000, and amounting almost exactly to £14,000, the total received to date being £128,000.

The motion for the adoption of the Accounts, having been seconded by Sir Basil Mayhew, was then put and carried unanimously.

THE ANNUAL REPORT

The annual report for 1934 was adopted unanimously while the report of revenue and propaganda committees was presented and a resolution passed unanimously that it should be published. Lord Donoughmore then presented the report on

THE SILVER JUBILEE DISTRIBUTION

when he moved the recommendation that the sum of £120,000, representing the unspent income balances of the last twenty-five years and the profits from the Jubilee seats, together with any other sums which might be received in connexion with the Jubilee and which the general council might allocate for the purpose, be made the subject of a special Silver Jubilee Distribution in the autumn among the hospitals of London, in aid of programmes of capital expenditure already notified to the distribution committee by May 28th, the date of the council meeting.

The recommendation was seconded by Sir Ernest Pooley and carried.

The meeting closed with a vote of thanks to his Royal Highness, which was proposed by the Bishop of London, and seconded by Prof. Winifred Cullis. The vote having been carried with acclamation, His Royal Highness briefly acknowledged the vote.

MEDICAL NEWS

ociety of Apothecaries of London

At recent examinations the following candidates were ccessful :—

Surgery.—A. Aspinall, Univ. of Manch.; W. H. Bayley, . Thomas's Hosp.; W. C. Campbell, Univ. of Birm.; F. wking, Univ. of Oxf. and St. Bart.'s Hosp.; H. N. Levitt, y's Hosp.; J. Mason, Middlesex Hosp.; A. G. Sweetapple, iv. of Sydney; and R. L. Walmsley, Univ. of Camb. and iv. of Leeds.

Medicine.—H. Burrows, Univ. of Manch.; E. H. E. Cross, . Mary's Hosp.; R. N. Crossley, Univ. of Manch.; C. S. J. ndekar, Univ. of Durham; H. O. Dole, Univ. of Manch.; . A. Kamel, Welsh National School of Medicine; B. S. Minden, . George's Hosp.; J. C. Paterson, Univ. of Oxf. and . George's Hosp.; A. G. Sweetapple, Univ. of Sydney; and W. Van Mentz, London Hosp.

Forensic Medicine.—N. A. Bicchieri, St. George's Hosp.; . O. Dole, Univ. of Manch.; and A. G. Sweetapple, Univ. of dney.

Midwifery.—F. Brodahl and E. T. Garthwaite, St. Bart.'s osp.; W. J. Pinto, Univ. of Madras; A. G. Sweetapple, iv. of Sydney; P. A. Walshaw, Univ. of Leeds; and J. L. redden, London Hosp.

The following candidates, having completed the final amination, are granted the diploma of the society titling them to practise medicine, surgery, and idwifery :—

W. C. Campbell, E. H. E. Cross, R. N. Crossley, C. S. J. andekar, J. Mason, B. S. Minden, J. C. Paterson, A. G. eetapple, and J. L. Wredden.

anchester Hospital Scheme

The Manchester public health committee are considering £50,000 scheme for the construction of a new wing at aguley Sanatorium.

University of Glasgow

Dr. Arthur James Ballantyne has been appointed the first holder of the new chair of ophthalmology established in the university under the terms of the will of Dr. Gavin Tennant.

Dr. Ballantyne was born in 1876 and received his medical education at the universities of Glasgow and Vienna. After graduating in 1898 he held house appointments at the Royal Infirmary, and in 1901 went as house surgeon to the Glasgow Eye Infirmary, where he joined the honorary staff in the following year. In 1909 he was appointed professor of physiology

TUESDAY, MAY 28TH

Medical Reports and Remand of Prisoners

Captain **CUNNINGHAM-REID** asked the Home Secretary whether he had considered the recommendation contained in the Report of the Commissioners of Prisons for 1933 that it would be an advantage in police-court cases if the usual period of remand for eight days on bail or in custody could be extended to 14 or 21 days, without producing the prisoner, if the court was satisfied by a medical report that such extension was desirable to ascertain the mental condition of the prisoner; and whether he proposed to accept this recommendation and implement it by the introduction of the necessary legislation.—Sir J. **GILMOUR** replied: This recommendation has been noted for consideration when there is an opportunity for legislation, but I cannot say when it will be possible to give effect to it.

Casual Labourer's Death at Portsmouth

Mr. **THORNE** asked the Home Secretary if he had received a report from his factory inspector in connexion with the death of a casual labourer at Portsmouth who was assisting to carry an acetylene welding-plant; if he could state the cause of the accident; and whether he had any record of similar cases.—Sir J. **GILMOUR** replied: I have received a preliminary report from which it appears that the accident occurred in an unusual manner owing to sparks entering an acetylene generator which was not altogether cleared of gas. The case will be followed up with a view to the prevention of any similar accident.

Shorter Hours in Industry

Captain **FULLER** asked the Minister of Labour if any steps were now being taken through the International Labour Office to negotiate agreements for the shortening of hours in industry.—Mr. R. S. **HUDSON** (Parliamentary Secretary to the Ministry of Labour) replied: Proposals designed to secure International Conventions limiting hours of work in Public Works undertaken or subsidised by Governments, and in the iron and steel, building and contracting, glass bottle, and coal-mining industries, are to be considered at the International Labour Conference which opens in Geneva at the beginning of next month.

KING EDWARD'S HOSPITAL FUND FOR LONDON

THE annual meeting of the Fund was held at St. James's Palace on Tuesday when H.R.H. the Prince of Wales, the president of the Fund, presided over the meeting. He commenced by reading a resolution of congratulation to the King, on the occasion of his Silver Jubilee, which he had already forwarded to His Majesty, and to which the gracious reply from the King was received confirming His Majesty's deep personal interest in the Fund, and the satisfaction with which, as a past president for nine years, he had watched its steady growth until it had become an essential part of the voluntary hospital system of London.

His Royal Highness continued by stating the King's wish that his Silver Jubilee should not be marked by any general appeal on behalf of hospitals, but by the foundation of a new Trust Fund, with a new purpose.

"It is indeed natural," said His Royal Highness, "that this Council should wish to mark the occasion in some exceptional way. The King's Fund was founded to commemorate the Diamond Jubilee of Queen Victoria in 1897; it was augmented by the Coronation gift to King Edward the Seventh in 1902; and its last special appeal was for the Thank-offering Fund for the recovery of King George in 1929. The King was its President for nine years, and since his accession has taken an active interest as its Patron.

"Briefly, the proposal is this. During the 25 years of the King's reign the ordinary distribution has been increased from £150,000 a year to £300,000. In other words, it has been exactly doubled. But every year a small margin of the annual income has been kept in hand; a kind of estimated budget surplus. This policy has been successful, and the small margins have accumulated. During the post-war financial crisis a great inroad was made into the reserves by the emergency distribution of £250,000 in 1920, itself a striking illustration of the value of a central fund. But since 1920 the small annual margins have again been accumulating, and they have now reached a total of about £109,000.

"There is also another sum of money available, more closely associated with the Jubilee. It arises from the sale of the seats which were offered to the King's Fund by His Majesty's Office of Works for the processions of May 6th and May 9th, and with the personal approval of the King. This comes to about another £11,000, and raises the available total to approximately £120,000.

"This additional distribution will have a special object. The hospitals themselves have, in spite of the financial depression, gone on extending their work and also increasing their income. The result has been that the *hospitals, like the King's Fund*, have, taken as a whole, just balanced their budgets, with a small margin on *the right side*, in spite of deficits at some hospitals where the circumstances are exceptional. The figures for 1934 tell the same tale. It has been the result of a great and most creditable effort on the part of the hospitals and their subscribers, among whom I wish particularly to mention their own patients.

"But this is not enough. It is true that hospital income has just kept pace with the increased expenditure, and there have been some very successful appeals for reconstruction and extension. But a good deal of urgent work in the way of improvements to buildings and equipment has fallen into arrears.

"The money we have available will be enough to enable us to help with some of this work, though not with all of it.

"The proposal, therefore, is that the sum of £120,000, representing the unspent income balances of the last 25 years and the profits from the Jubilee seats, together with any other sums which may be received in connexion with the Jubilee and which the General Council may allocate for the purpose, should be made the subject of a special Silver Jubilee Distribution in the autumn among the hospitals of London, in aid of programmes of capital expenditure already notified to the Distribution Committee."

His Royal Highness went on to say that the accounts showed the income for the year to have just covered the distribution, such small surpluses as it was proposed to distribute having been accumulated before the crisis of 1931, when the annual grants were increased at one bound from £275,000 to £300,000. Since that effort, he said, the margin of income over distribution had been very narrow.

He referred to the out-patients' arrangements committee of the Fund whose report dealt with time-saving methods in the out-patient departments of hospitals, especially the reduction of waiting at the dispensary stage of procedure. The committee had collected information from all the hospitals, had made visits to certain of them, and had circulated their report for the observation of the institutions. His Royal Highness continued:—

"I have now some gratifying news. You already know that of recent years various donors have entrusted the King's Fund with the administration of sums of money for special purposes connected with hospitals. Another example of this has just occurred. The Bank of England have asked King Edward's Hospital Fund to deal on their behalf with appeals which they may receive from London hospitals. With this object the Bank have set aside and paid to the Fund a sum for distribution, this being the first of seven annual payments which they have undertaken to make to the Fund for this urpose. The sum includes the Bank's usual annual ubscription to the King's Fund, and certain annual ubscriptions which the Bank has previously made direct certain London hospitals. The balance is to be distributed by the Fund in response to such appeals from ondon hospitals as the Bank may receive and forward the Fund for consideration. The hospitals to be ssisted under the latter head, and the allocation among uch hospitals, will be determined by the Fund at its scretion.

"It is satisfactory to know that the amount thus ntrusted to the King's Fund represents an increase upon e average annual total sum hitherto dispensed by the ank in direct donations. These grants will be decided the autumn, just before our ordinary distribution. They ill be quite distinct from the ordinary grants, and will ach the selected hospitals as donations from the Bank England, per King Edward's Hospital Fund. I should ke, in your name and in mine, to express our appreciation the action of the Bank of England, and the pleasure it ill give us to use on their behalf all our knowledge of e circumstances of the various hospitals."

His Royal Highness then recorded the loss by eath of prominent members of the council since e last meeting, making special reference to Lord omerleyton, the senior honorary secretary, Mr. hitley, the chairman of the Parliamentary Committee f the council, and Sir John Rose Bradford, chairman f the out-patients' arrangements committee, adding hat he had appointed Lord Macmillan in place of Ir. Whitley, and Dr. Morley Fletcher in place of ir John Rose Bradford.

ACCOUNTS FOR 1934

Sir Edward Peacock, hon. treasurer of the Fund, in moving he adoption of the accounts, said that at the distribution December there was still a small deficit, but this was overed before the end of the year, though with a margin f only £426. The total amount distributed was again 320,000. Annual subscriptions were £200 more than 1933 and donations £1,600 more. Legacies amounted o £77,000. During the past seven years the lowest igure for legacies had been £58,000, and the average had een £70,000. There was no doubt that the King's Fund, ith its annual grants to 200 hospitals and convalescent omes, made a strong appeal to testators who wished to leave legacies or residues to charity, but had no particular institution in their minds. But they would be glad to see a larger proportion of the increased distribution provided for by annual subscriptions. He would like to refer to the advantages, both to subscribers and to the Fund, from the use of seven-year agreements, which enabled income tax and surtax to be saved. Last year the Fund received 67 annual subscriptions under agreements of that kind, ranging from £1 1*s.* to £4000, and amounting almost exactly to £14,000, the total received to date being £128,000.

The motion for the adoption of the Accounts, having been seconded by Sir Basil Mayhew, was then put and carried unanimously.

THE ANNUAL REPORT

The annual report for 1934 was adopted unanimously while the report of revenue and propaganda committees was presented and a resolution passed unanimously that it should be published. Lord Donoughmore then presented the report on

THE SILVER JUBILEE DISTRIBUTION

when he moved the recommendation that the sum of £120,000, representing the unspent income balances of the last twenty-five years and the profits from the Jubilee seats, together with any other sums which might be received in connexion with the Jubilee and which the general council might allocate for the purpose, be made the subject of a special Silver Jubilee Distribution in the autumn among the hospitals of London, in aid of programmes of capital expenditure already notified to the distribution committee by May 28th, the date of the council meeting.

The recommendation was seconded by Sir Ernest Pooley and carried.

The meeting closed with a vote of thanks to his Royal Highness, which was proposed by the Bishop of London, and seconded by Prof. Winifred Cullis. The vote having been carried with acclamation, His Royal Highness briefly acknowledged the vote.

Dr. Arthur James Ballantyne has been appointed the first holder of the new chair of ophthalmology established in the university under the terms of the will of Dr. Gavin Tennant.

Dr. Ballantyne was born in 1876 and received his medical education at the universities of Glasgow and Vienna. After graduating in 1898 he held house appointments at the Royal Infirmary, and in 1901 went as house surgeon to the Glasgow Eye Infirmary, where he joined the honorary staff in the following year. In 1909 he was appointed professor of physiology at the Anderson College of Medicine, and from 1915 to 1920 was professor of ophthalmology both there and at St. Mungo's College. Since the latter year he has been lecturer in ophthalmology at the University. Dr. Ballantyne is now surgeon to the Eye Infirmary, consulting ophthalmological surgeon to the Western Infirmary, and honorary consulting ophthalmological surgeon to the Royal Maternity and Women's Hospital. He has been a vice-president of the Ophthalmological Society of the United Kingdom and of the Section of Ophthalmology of the Royal Society of Medicine, and besides many contributions to medical journals he is the author of a "Pocket Book of Ophthalmology."

Charing Cross Hospital Medical School

Dr. Andrew Topping, of the public health department of the London County Council has been appointed lecturer in hygiene and public health at this school in succession to the late Dr. C. W. Hutt.

British Postgraduate Medical School

An intensive refresher course intended primarily for general practitioners will be held at this school from June 17th to 29th. Particulars may be had from the dean of the school, Ducane-road, London, W.12, and early application is recommended because membership of the course is limited.

National Hospital for Diseases of the Heart

A special course will be held at this hospital from June 24th to July 5th, both mornings and afternoons. The membership is limited to twenty, and application should be made to the dean of the hospital, Westmoreland-street, London, W.1.

International Congress in Switzerland

From Sept. 9th to 14th a congress will be held at Montreux at which various medical subjects will be introduced by speakers from many countries, including Sir Henry Dale, F.R.S., from England. Particulars may be had from the secretariat of the Semaine Médicale Internationale en Suisse, Klosterberg 27, Basle.

Maternity and Child Welfare Conference

The National Conference on Maternity and Child Welfare will be held at the County Hall, Westminster Bridge, S.E., from July 1st to 3rd, under the presidency of Sir Hilton Young, the Minister of Health. A short post-graduate course for medical practitioners will be held on June 29th and 30th. Particulars may be had from the National Association for the Prevention of Infant Mortality, 117, Piccadilly, London, W.1.

Health Congress at Harrogate

The Royal Institute of Public Health and the Institute of Hygiene are next week holding their first joint congress, and the proceedings open on June 4th at Harrogate, with Lord Harewood as president. The five sections are devoted to state medicine and industrial hygiene, women and children, and the public health, tuberculosis, rheumatism and allied diseases, and hydrology, climatology and meteorology, and their presidents are respectively, Prof. J. Johnstone Jervis, Lady Evelyn Collins, Sir Pendrill Varrier-Jones, Sir William Willcox, and Sir Henry Gauvain. The arrangements include a garden party at Harewood House, a civic reception, a visit to Knaresborough, and many excursions in the neighbourhood.

Inquests in London

During the year 1934 there were 8548 deaths reported to London coroners, 15 more than in 1933. Of these deaths 721 took place in mental hospitals, 2351 in other hospitals and institutions. In the exercise of their discretion the coroners held inquests in 3455 cases or 88 less than last year. Post-mortem examination was directed by the coroner in 82 per cent. of inquest cases and 64 per cent. of the cases in which no public inquiry was thought necessary. A verdict of murder was returned in 11 cases, of suicide in 690 cases (70 less than last year). Deaths from want of attention at birth increased from 28 to 32. In all 1925 people met their death by accident (40 more than last year). There were 50 deaths by drowning. A verdict of "death from natural causes" was returned in 543 cases and there were 7 verdicts of "cause of death unknown." Of the total inquests 992 were held with juries. The information is taken from a report to the public control committee of the London County Council.

Dr. E. P. Cathcart, F.R.S., regius professor of physiology in the University of Glasgow, has been appointed chairman of the Committee on Scottish Health Services in succession to the late Sir John Dove-Wilson.

Cambridge Graduates Medical Club

A club dinner will be held at Sidney Sussex College, Cambridge, on Friday, June 28th, 7.30 for 7.45 P.M., at which Sir Walter Langdon-Brown, regius professor of physic, will preside. Accommodation for the night can be provided at the college. Cambridge graduates not already members of the club should communicate with one of the hon. secretaries, Dr. F. G. Chandler, 1, Park-square, London, N.W. 1, or Mr. W. D. Doherty, 10, Upper Wimpole-street, W. 1.

Ophthalmological Congress in Berlin

The second international Kongress für Irisdiagnostik, which originally was to have been held in May, will now take place in Berlin from Sept. 12th–15th. The secretary of the congress may be addressed at Leubnitzerstr. 2, Dresden A 24.

Research Defence Society

The annual general meeting of this society will be held at the London School of Hygiene and Tropical Medicine, Keppel-street, London, on Wednesday, June 12th, when the chair will be taken by the president, Lord Lamington. The ninth Stephen Paget Memorial Lecture will be delivered by Sir Frederick Hobday, principal and dean of the Royal Veterinary College, whose address on the relief of animal suffering will be illustrated by lantern and cinematograph.

London and Counties Medical Protection Society Limited

An extraordinary general meeting of this society will be held at Victory House, Leicester-square, London, on Wednesday, June 12th, at 3.30 P.M., when the annual general meeting will follow. The business of the meeting will be, in addition to receiving and adopting the annual report and balance sheet, an election to fill the place of the late Sir John Rose Bradford.

Opening of the New Middlesex Hospital

Last Wednesday the new Middlesex Hospital was declared open by the Duke of York, who in 1928 laid its foundation stone. The hospital has cost £1,250,000, of which £300,000 was received from an anonymous donor, and £200,000 from Mr. E. W. Meyerstein. The institute which bears his name was the gift of Sir John Bland-Sutton; Mr. S. A. Courtauld built the institute of bio-chemistry and endowed the chair of bio-chemistry; and Mr. W. H. Collins has given the new X ray diagnostic department.

The Duke of York, who was accompanied by the duchess, was met in the courtyard of the hospital by H.R.H. Prince Arthur of Connaught, president of the hospital. Prince Arthur, in welcome, pointed out that the reign whose jubilee had just been celebrated had made remarkable attempts to improve the condition of the people as a whole and to bring about a clearer realisation of the responsibilities of wealth. The Duke of York, in declaring the buildings open, congratulated the generous supporters of the voluntary hospital system on their great accomplishment at the Middlesex, and, speaking as president of the British Empire Cancer Campaign, pointed to the important part played by the hospital in the fight against that disease. Their Royal Highnesses then made a tour of the hospital and many of the visitors followed suit.

Demonstrations of Contraceptive Technique

On Thursday, June 6th, at 2.30 p.m., a practical demonstration of the technique of the use of a variety of contraceptive methods will be given by Mrs. Marie Stopes, D.Sc., and Dr. Evelyn Fisher at the Constructive Birth Control Clinic, 108, Whitfield-street, London, W.1. Those attending will be enabled to practise the application of various contraceptive devices. Requests for tickets (which will be supplied to medical practitioners and senior students only) should be made in writing to the hon. secretary of the clinic.

rporation of the City of London: Public Health Committee

A presentation luncheon was given on Wednesday t to the past chairman of this committee, Sir Percy epherd, when Captain G. S. Elliston, M.P., took the air and the Lord Mayor and Sheriffs of the City were ıong the guests. After the loyal toast, Mr. Geoffrey akespeare, M.P., Parliamentary Secretary to the nistry of Health, proposed the health of the Lord Mayor, d spoke eloquently of the duties that devolved on the rporation of the City in respect to public health, point- g out how multifarious were the directions in which e services of the committee were required. The resi- nt population of the City might be small, but though ly 10,000 persons slept in the City, the better part of million passed their working lives in it, while the food pplied in bulk were in relation not to the residents but the enormous county of London. He spoke of the ork that had been put in by the House of Commons regard to the Housing Bill, work now nearing its com- etion. Captain Elliston, proposing the health of the ast chairman, Sir Percy Shepherd, related in an amusing ay the duties of the chairman of the public health com- ittee to the audience, testifying to the extremely satis- ctory way in which his predecessor had discharged those uties. As far as they concerned the resident population at population was in charge of the committee from con- eption to cremation. Sir Percy Shepherd having replied, aptain Elliston proposed the health of the guests. ord Balfour of Burleigh in reply spoke of the merits f the Housing Bill and the work which the measure as resented implied, but thought that after its issue from he House of Commons the House of Lords might have omething to say. Sir George Truscott, senior alderman, roposed the health of the chairman, to which Captain lliston briefly replied.

ebanon Hospital for Mental Diseases

At the thirty-sixth annual meeting, held at Friends House, Euston-road, on May 20th, the chairman, Lord Alness, said that the history of this hospital was a romance. The acorn of 1896 had in 1935 become a spreading oak tree. In its inception two eminent Scottish psychiatrists—Thomas Clouston and David Yellowlees—now long deceased, had played a leading part; it was the latter who conceived the idea of building the hospital on the cottage or pavilion system. In memory of them the new building opened in November, 1933, had been named the Scottish House. But despite the extensions of recent years there was still need for a larger institution. In Syria there was only one bed in mental hospitals for every 16,000 people. After the audience had stood in respect for the memory of Dr. Henry Watson Smith, medical director for 25 years, who died suddenly shortly after the last annual meeting, Dr. Percy Smith presented the medical report, and Dr. E. W. G. Masterman the report of the general committee. Dr. Masterman said that Dr. R. Stewart Miller, who took up duty as director last September, was intimately acquainted with mental diseases in the Near East through his work as head of the Government mental hospital at El Khanka, near Cairo; he spoke Arabic and French, and was familiar with the officials and ways of these countries. Soon after his arrival in Syria, Dr. Miller had been appointed lecturer in mental diseases at the University of Beirût, and mental expert to the *criminal court*. The director's report showed the average number of patients in residence during the four quarters of the last twelvemonth to be 273, 279, 307, and 314. The ever-increasing demand for accommodation had required the addition of new wings to two of the older houses, enlargement of the central kitchen and laundry, a new central dining hall, and an isolation pavilion (for 32 patients and staff). The new water-supply from the mountains had been of great value. Fourth-year medical students from Beirût continued to attend for clinical demonstrations, and a course of lectures on mental nursing was being given to senior students of the College of Nursing, with practical demonstrations in the wards of the hospital. During the year 188 patients had been admitted (130 men, 58 women), making a total of 461 under treatment; 115 patients had been discharged, and of these 52 were recovered, 30 relieved, 27 not improved, 6 not insane. There had been 29 deaths. The patients came from all over the Near East and were mainly native to those parts, but sometimes persons temporarily resident in the country. The most frequent type of disorder was the schizophrenic reaction (77) and next the affective reaction (38).

Medical Diary

SOCIETIES

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.
Wednesday, June 5th.
Surgery. Provincial Meeting in Cardiff.
History of Medicine.—5 P.M., Dr. J. D. Comrie: Eighteenth Century English Medicine.

BIOCHEMICAL SOCIETY.
Friday, June 7th.—2.30 P.M. (Department of Medical Chemistry, University of Edinburgh), Short Communications.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

WEST LONDON HOSPITAL POST-GRADUATE COLLEGE, Hammersmith, W.
Monday, June 3rd.—10 A.M., Medical Wards, Skin Clinic. 11 A.M., Surgical Wards. 2 P.M., Surgical and Gynæcological Wards, Eye and Gynæcological Clinics. 4.15 P.M., Mr. Green-Armytage: Pelvic Ruptures.
Tuesday.—10 A.M., Medical Wards. 11 A.M., Surgical Wards. 2 P.M., Throat Clinic. 4.15 P.M., Dr. Redvers Ironside: Diseases of the Sympathetic Nervous System.
Wednesday.—10 A.M., Medical and Children's Wards, Children's Clinic. 2 P.M., Eye Clinic, Gynæcological Operations.
Thursday.—10 A.M., Neurological and Gynæcological Clinics. Noon, Fracture Clinic. 2 P.M., Genito-urinary and Eye Clinics. 3.45 P.M., Venereal Diseases.
Friday.—10 A.M., Skin Clinic. Noon, Lecture on Treatment. 2 P.M., Throat Clinic.
Saturday.—10 A.M., Surgical and Children's Clinics, Medical Wards.
Daily at 2 P.M., Operations, Medical and Surgical Clinics.
The lectures at 4.15 P.M. are open to all medical practitioners without fee.

SOUTH-WEST LONDON POST-GRADUATE ASSOCIATION.
Wednesday, June 5th.—4 P.M. (St. James' Hospital, Ouseley-road, Balham, S.W.), Dr. C. E. Lakin: Demonstration of Medical Cases.

LONDON HOMŒOPATHIC HOSPITAL, Great Ormond-street, W.C.
Thursday, June 6th.—5 P.M., Dr. James Rishworth and Dr. Agnes Moncrieff: Homœopathy in General Practice. Dr. N. H. Hatfield: A Beginner's Difficulties.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C.
Thursday, June 6th.—2 P.M., Mr. A. Simpson-Smith: Clinical Cases. 3 P.M., Dr. A. Signy: Typing of Organisms and Tests of Virulence.
Out-patient Clinics daily at 10 A.M. and Ward Visits (except on Wednesday) at 2 P.M.

ROYAL INSTITUTE OF PUBLIC HEALTH AND THE INSTITUTE OF HYGIENE.
Tuesday, June 4th, to Sunday.—Health Congress at Harrogate.

INSTITUTE OF CHILD PSYCHOLOGY.
Wednesday, June 5th.—6.15 P.M. (Friends House, Euston-road, N.W.), Dr. Margaret Lowenfeld: Play in Childhood. 8.15 P.M., Dr. Hazel Chodak Gregory: The Place of Habit in Development.

INSTITUTE OF PATHOLOGY AND RESEARCH, St. Mary's Hospital, W.
Thursday, June 6th.—5 P.M., Sir Henry Dale, F.R.S. The Active Substances in Ergot: a Thirty Years' Review.

INSTITUTE OF MEDICAL PSYCHOLOGY, Malet-place, W.C.
Wednesday, June 5th.—3 P.M., Dr. H. Crichton-Miller: Alcoholism and Drug Addictions. 4.30 P.M., Dr. Cedric Shaw: Fatigue States.

CHADWICK LECTURE.
Thursday, June 6th.—5 P.M. (The Chelsea Physic Garden, Swan-walk, S.W.), Sir John Russell, F.R.S.: Modern Changes in Food Production.

UNIVERSITY OF DURHAM COLLEGE OF MEDICINE.
Sunday, June 2nd.—10.30 A.M. (Newcastle General Hospital), Mr. A. Logan: Surgical Cases.

UNIVERSITY OF BIRMINGHAM.
Tuesday, June 4th.—3.30 P.M. (General Hospital), Dr. B. C. Tate: Demonstration of Skin Cases.
Friday.—3.30 P.M. (Queen's Hospital), Prof. Philip Cloake: Circulatory Disorders of the Extremities.

ROYAL INFIRMARY, Manchester.
Tuesday, June 4th.—4.15 P.M., Mr. W. M. Sutherland: Carcinoma of the Colon.

Appointments

Dalton, H. W., M.B. Dub., has been appointed Junior Assistant Pathologist to the Royal Infirmary, Sheffield.

Denny-Brown, D., M.B. N.Z., M.R.C.P. Lond., Consulting Neurologist to the Royal Hospital and Home for Incurables, Putney.

Gillespie, N. A., B.M. Oxon., Hon. Anæsthetist to the Princess Beatrice Hospital, London.

Hudson, M. W. P., M.B. Lond., Hon. Anæsthetist to the Princess Beatrice Hospital, London.

Lightwood, R. C., M.D., M.R.C.P. Lond., Hon. Physician for Diseases of Children to the Bolingbroke Hospital, London.

Roth, P. B., M.B. Aberd., F.R.C.S. Eng., Hon. Orthopædic Surgeon to the Burslem Haywood and Turnstall War Memorial Hospital.

Wiles, Philip, M.S. Lond., F.R.C.S. Eng., Assistant Orthopædic Surgeon to the Middlesex Hospital.

Williams, Bryan, M.D., F.R.C.S. Edin., M.C.O.G., Hon. Obstetric Physician to the Sussex Maternity and Women's Hospital, Brighton.

Certifying Surgeons under the Factory and Workshop Acts: Dr. F. Hunter (Turriff District, Aberdeenshire); Dr. H. G. McPherson (Stonehaven District, Kincardineshire); Dr. T. A. Shaw (Stromness District, Orkney); Dr. J. H. Wardrop (Ellon, Aberdeenshire); Dr. J. A. Screech (Twickenham, Middlesex); and Dr. Beatrice M. Sellar (Aberlour, Banffshire).

London County Council Hospital Service.—The following appointments are announced:—

Anderson, J. S., M.D. Aberd., D.P.H., Medical Superintendent, Grove Hospital;

Morris, A. D., M.D. Brussels, Medical Superintendent, St. Leonard's Hospital; and

McKee, G. K., F.R.C.S. Eng., Senior Assistant Medical Officer, Grade II., St. Luke's, Lowestoft.

Vacancies

For further information refer to the advertisement columns

Accrington, Victoria Hospital.—H.S. £150.

Albert Dock Hospital, Connaught-road, S.E.—Res. M.O. At rate of £110.

Barnsley, Beckett Hospital and Dispensary.—H.P. £200.

Barnstaple, North Devon Infirmary.—Res. M.O. £150.

Bath Royal United Hospital.—H.P. £150.

Bedford County Hospital.—First and Second H.S. At rate of £155 and £150 respectively.

Belfast, Queen's University.—Tutor in Obstetrics. £200.

Belfast, Royal Maternity Hospital.—Res. H.S. At rate of £50.

Birmingham, Imperial Chemical Industries, Limited.—Asst. M.O. £500.

Birmingham, Selly Oak Hospital.—Res. Physician. £650.

Birmingham and Midland Hospital for Women.—H.S. At rate of £100.

Blackburn Royal Infirmary.—Res. H.S. and Cas. O. At rate of £175 and £150 respectively.

Bradford Royal Eye and Ear Hospital.—H.S. £160.

Brighton, Sussex Eye Hospital.—Hon. Clin. Asst.

Bristol p in Physiology. £400.

Bucks . County M.O. and M.O.H. £800.

Cancer , *S.W.*—H.S. At rate of £100.

Canterbury, Kent and Canterbury Hospital.—Two H.S.'s. Each at rate of £125.

Central London Throat, Nose, and Ear Hospital, Gray's Inn-road, W.C.—Two Hon. Assts. for Out-patient Dept.

Charing Cross Hospital, W.C.—Asst. Physician.

Chesterfield and North Derbyshire Royal Hospital.—Cas. O. Also H.S. to Ear, Nose, and Throat Dept. At rate of £200 and £150 respectively.

City of London Hospital for Diseases of the Heart and Lungs, Victoria Park, E.—H.P. At rate of £100.

City of Lo *oad, E.*—Asst. M.O. £250.

Connaught *E.*—H.S. At rate of £100.

Croydon M *ham.*—Med. Supt. £1100.

Derby, Bretby Hall, Orthopædic Hospital, near Burton-on-Trent. Locum Res. Asst. M.O. At rate of £350.

Doncaster Royal Infirmary.—H.S. to Eye, Ear, Nose, and Throat Dept. £175.

Dorchester, Dorset County Hospital.—H.S. At rate of £160.

Downpatrick, Down Mental Hospital.—Res. Med. Supt. £800. Also Asst. M.O. £350.

Dreadnought Hospital, Greenwich.—Hon. Gynæcologist. Also H.P. and H.S. Each at rate of £110.

Dudley Guest Hospital.—Hon. Physician and Hon. Surgeon.

Dulwich Hospital, S.E.—H.P. At rate of £120.

Essex C.C. Oldchurch Hospital, Romford, &c.—Asst. M.O. £600.

Gateshead Mental Hosp.—Med. Supt. £800. Also Asst. M.O. £400.

General Post Office, Headquarters Medical Branch.—A.M.O. £500.

Hartlepools Hospital.—H.S. At rate of £150.

Hertford County Hospital.—Sen. H.S. Also H.S. At rate of £200 and £180 respectively.

Hospital for Tropical Diseases, Gordon-street, W.C.—Two H.P.'s. Each at rate of £120.

Hospital for Women, Soho-sq., W.—Res. M.O. At rate of £100.

Hull Municipal Maternity Home and Infants' Hospital.—Jun. Res. M.O. At rate of £100.

Indian Medical Service.—Commissions.

Jersey General Hospital and Poor Law Infirmary.—Res. M.O. £100–£200.

Keighley and District Victoria Hosp.—Res. M.O. At rate of £180.

King's College Hospital, Denmark Hill, S.E.—Asst. Physician.

Leeds City Hospital for Infectious Disease.—Med. Supt. £810.

Leeds Hospital for Women.—Hon. Anæsthetist.

Leicestershire and Rutland Mental Hospital, Narborough.—Asst. M.O. £350.

L.C.C.—Jun. M.O.'s. £7 a week. Also Temporary District M.O.'s. At rate of £175.

Liverpool, David Lewis Northern Hospital.—Cas. O. and H.S. £120 and £80 respectively.

London University.—Laura de Salleeto Studentship. £150. Also University Readership in Surgery. £800.

Macclesfield General Infirmary.—Second H.S. At rate of £150.

Manchester, St. Mary's Hospitals.—Two H.S.'s for Whitworth-street West Hospital. Also Two H.S.'s for Whitworth Park Hospital. Each at rate of £50.

Mid-Wales Counties Mental Hospital, Talgarth, Breconshire.—Asst. M.O. £400.

National Temperance Hospital, Hampstead-road, N.W.—Cas. O. and H.P. At rate of £120 and £100 respectively.

Newcastle-upon-Tyne, Royal Victoria Infirmary.—Two Med. Regs. Each £250.

Northampton, County Mental Hospital, Berrywood.—Med. Supt. £900.

Oldham Royal Infirmary.—H.S. At rate of £175.

Plymouth, Prince of Wales's Hospital.—H.P., Res. Anæsthetist. Also H.S. to Spec. Depts. Each at rate of £120.

Princess Elizabeth of York Hospital for Children, E.—H.P. and H.S. Each at rate of £125.

Princess Louise Kensington Hospital for Children, St. Quintin-avenue, W.—H.S. At rate of £100.

Queen Charlotte's Maternity Hospital, Marylebone-road, N.W.—Registrar. 20 guineas.

Queen Mary's Hospital for the East End, E.—Res. M.O. and Two Cas. O.'s. Each £150. Also Two H.S.'s, H.P., Obstet. H.S., and Res. Anæsthetist. Each £120.

Royal College of Physicians of London.—Leverhulme Research Scholarship. £500.

Royal Masonic Hospital, Ravenscourt Park, W.—Res. Surg. O. At rate of £250.

Royal Northern Hospital, Holloway, N.—H.S. and H.P. Each at rate of £70.

Ryde, Royal Isle of Wight County Hospital.—Res. H.S. At rate of £180.

St. David's Hospital, Silver-street, N.—Temp. Visiting M.O. At rate of £250.

St. Mary's Hospital for Women and Children, Plaistow, E.—Pathologist. £200.

St. Nicholas Hospital, Plumstead, S.E.—Temp. Asst. M.O. At rate of £250.

St. Peter's Hospital for Stone, &c., Henrietta-street, W.C.—Clin. Assts. to Hon. Staff.

Salford Royal Hospital.—Two H.S.'s. Each at rate of £125.

Salisbury General Infirmary.—Res. M.O. £250.

Salvation Army, Mother's Hospital, Lower Clapton-road, N.—Two Jun. Res. M.O.'s. At rate of £80.

Samaritan Free Hospital for Women, Hon. Surgeon to Out-patients. A

Sheffield Royal Infirmary.—Two H.S. H.S. Also Asst. Cas. O. Each at rate of £80.

£600.

sst. M.O. £300.

At rate of £200.

Stockport Infirmary.—Res. Surg. O. £250.

Stoke-on-Trent, Longton Hospital.—H.S. £160.

Stretford Memorial Hospital.—Surgical Asst. 50 guineas.

Surrey County Council.—Two Asst. M.O.'s. Each £600.

Swindon and North Wilts Victoria Hosp.—Visiting Radiologist.

Warwick, King Edward VII. Memorial Sanatorium, Hertford-hill. Jun. Asst. M.O. At rate of £200.

West Bromwich and District General Hospital.—H.P. At rate of £200.

West Bromwich, Hallam Hospital.—Res. H.P. At rate of £200.

West London Hospital, Hammersmith-road, W.—Chief Clin. Asst. in X Ray Dept. £125. Cas. O. £250. Also H.P. and 2 H.S.'s. Each at rate of £100.

West Riding Mental Hospital, Wakefield.—Fifth Asst. M.O. £350.

Weston-super-Mare General Hospital.—Res. H.P. £150.

Willesden General Hospital, Harlesden-road, N.W.—Res. Cas. O. At rate of £100.

Windsor, King Edward VII Hospital.—Reg. M.O. £150.

Wolverhampton Royal Hospital.—H.S. At rate of £100.

Worksop, Victoria Hospital.—Sen. H.S. At rate of £150.

The Chief Inspector of Factories announces vacancies for Certifying Factory Surgeons at Bury St. Edmunds (Suffolk) and Wainfleet (Lincolnshire).

Births, Marriages, and Deaths

BIRTHS

Birch.—On May 24th, at Liverpool, to Marjorie (née Bold), wife of C. Allan Birch, M.D., M.R.C.P., of a son.

Cursham.—On May 19th, at a Norwich nursing-home, the wife of Anthony Cursham, M.R.C.S. Eng., of a daughter.

DEATHS

Bevan.—On May 22nd, Richard Bevan, M.R.C.S. Eng., D.P.H., of East Sheen, S.W., aged 81.

Floyd.—On May 22nd, at Bournemouth, Stephen George Floyd, M.D. Lond., late of Grays, Essex, in his 68th year.

James.—On May 20th, at Cadmore End, Bucks, Walter Culver James, M.D. Aberd., F.R.C.S. Edin., late Surg. Colonel H.A.C.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Prevention of the Common Cold.—The suggestion made by "A London G.P." that thyroid extract may reduce the susceptibility to the common cold has reached a layman, who writes: "About fifteen years ago I had a breakdown in health, and a well-known London physician in Wimpole-street (who died a few months ago) prescribed, inter alia, gr. ¼ thyroid tabloids, one per diem. These I have taken from time to time and I have been free from colds. Before taking them I had colds rather frequently. It was not for these colds that I sought his advice."

NOTES, COMMENTS, AND ABSTRACTS

LIFE IN ABYSSINIA

MOST of us know about as little of Abyssinia as of Borneo, about which Dr. A. J. Copeland had something to tell us last week. A European woman dentist who practises in Addis Ababa writes of her own experience there in a German contemporary.[1] The vast majority of Abyssinians, Miss Dabbert says, live in round huts roofed with straw and without windows or chimneys. The walls are often defective, and through the cracks the cold night air penetrates. Adults and children sleep on straw mats or ox skins. The half-naked children, clad in rags, grow up in this primitive condition. Food consists chiefly of roast corn and a kind of cold pancake, with the occasional addition of a pepper sauce. There is no infant care and no idea of hygiene. The infant mortality is very high—about 50 per cent.—most of the deaths occurring in the first year. There is no family life, as marriages can be easily dissolved by either husband or wife without any legal complications; there are consequently no illegitimate children.

Through the mixture of races in Abyssinia there are many shades of skin colour, from light brown to the darkest ebony, but in spite of this nationalism is very strong, and is apparent in the dislike of European clothes and the love of the national dress. This consists of trousers, shirt, a kind of toga-like shawl of thin white cotton with a coloured border and a big wide brimmed hat. Soap is unknown, and the seeds of a plant called "Endott" are used instead. They are very effective. If water is handy the Abyssinian washes face and hands every morning and even the poorest peasant washes before and after meals. The feet are washed at night, especially between the toes to get rid of the jiggers. Bathing, especially in the hot springs with which the country is so well endowed, is indulged in frequently. The most famous of these springs is "Fel-Oha" at the capital Addis Ababa and the water comes from it boiling hot. There is a radioactive hot spring, good for rheumatism, at Errer Gotha, and a hot spring at Ambo also good for this complaint. There are special baths for hysteria and nervous diseases.

Though there are six big hospitals, several dispensaries and about 30 European doctors in the capital, the native healers have the confidence of the people, who will often return to them after having been successfully treated by Europeans. Miss Dabbert describes the methods used by native practitioners. Venereal disease is treated by secret remedies in which mercury plays the chief part. Cupping is carried out with an ox horn; the air and a definite quantity of blood is sucked up forcibly by the operator. Cauterization of the skin with a hot iron is widely used for the relief of pain. Most of the native remedies are herbal; decoctions, powders, and poultices made up from simple dried powders. There is here, she thinks, scope for research by pharmacologists. Superstition plays a large part in the preparation of their remedies. The plants have to be collected at a certain time of the day or night, and must be prepared and given in a secret manner. Cusso, the flower of a beautiful tree dried and made into a paste with water, is given for tape worms; the taste is very unpleasant and it often causes death from enteritis. Natives react quickly to drugs, and even severe wounds heal in a short time. Vaccination is practised, but with pus taken from a small-pox case. Circumcision is done by the priests 10 to 15 days after birth, and is very primitive. Leprosy is widespread; the natives have no remedy for this. There are two leper colonies, one organised by Franciscan monks and nuns, the other, very efficiently, by Americans.

Professional begging is rife, and compassion solicited for such ills as leprosy, elephantiasis and deformities.

At Addis Ababa, which is 8000 feet above sea level, pneumonia does badly and chronic lung cases do well. Typhus occurs in epidemics, worse in the rainy season. Tick fever also gives trouble in the rainy season. Typhoid is prevalent when the water begins to rise in the wells.

The Abyssinian government has started a network of hospitals throughout the country. There are also Catholic and Protestant medical missions. In the last ten years cultural progress has been rapid. The Abyssinians—or as they prefer to be called, the Ethiopians—are an energetic people, and it is, Miss Dabbert concludes, only a question of time for a proper organisation of medical services to be developed.

DR. J. H. WATSON

THE current number of *King's College Hospital Gazette* contains an amusing lecture delivered to the Listerian Society of the hospital by Mr. Ivor Back upon the personality of "my dear Watson," the companion and Boswell of Sherlock Holmes. And the actual introduction of Watson to Sherlock Holmes has been compared by a previous writer to that effected by Thomas Davies, the ex-actor and Covent Garden bookseller, of Boswell to Johnson. By industrious and ingenious extractions from the various publications dealing with the exploits of Sherlock Holmes, Mr. Back has been able to construct an accurate account of Dr. Watson, so that in regard to his medical school, the dates of his qualifications, and his tenure of appointments a paragraph suitable for insertion in the Medical Directory could be made, while out of other personal details as to his gallantry in the field, foreign travel, and marriages, a very readable autobiography for "Who's Who" could be constructed. Doubt, however, remains as to Dr. Watson's Christian names, which he would have removed had he corrected proofs for either of those valuable books of reference; in one story he is called John, and in another his first wife alludes to him as James, while the implication of "H" remains concealed. It would seem that Watson was an essentially modest man, for he certainly, as Holmes's biographer, wrote himself down as an ass, while Mr. Back makes of him, through documentary evidence, a brave man and a competent doctor.

BIDLOO AND COWPER

IN the March issue of the Annals of Medical History[1] there is an interesting essay by Dr. Fenwick Beekman, of New York, on systems of anatomy published at the end of the seventeenth century by Godfried Bidloo and William Cowper, in which the question of plagiarism by the latter is discussed in some detail. Bidloo, a Dutch anatomist, was born in 1649 and wrote his "Anatomia Humani Corporis" when he was about 36 years of age. In 1688 he became professor of anatomy at the Hague and came to England after the accession to the throne of William of Orange. The King consulted him with regard to his health when the Dutchman differed strongly from the English physicians who were also called into consultation. The King seems to have believed in his own countryman, for Bidloo was appointed general superintendent of civil and military hospitals in Holland, but on taking up office he got into trouble in connexion with the caricatures of certain judges. He was imprisoned but released at the instance of William and in 1693 was back in England where he was appointed inspector of military hospitals. In the following year he returned to Holland as professor of anatomy and surgery at Leyden, but being in constant attendance on William III. he neglected his professorial duties. We gather from Dr. Beekman's account of him that he was a difficult man, but he certainly was placed in difficult positions. His treatise on anatomy was recognised as valuable and it was illustrated in accordance with the grand but rather inaccurate manner of the time. The drawings are attributed to Gerard de Lairesse, and from them the trouble arose.

[1] Deut. med. Woch., April 26th, May 3rd, and 10th, 1935, pp. 682, 719, and 766.

[1] New York: Paul B. Hoeber, Inc. $2.50.

William Cowper, an English surgeon, was born 17 years later than Bidloo, and the first edition of his book "Anatomy of the Human Body" was published in 1698, by which time he was a well-known practitioner. This book was an advance on Bidloo's and in England was recognised at once as a standard work. But immediately on its publication arose a fierce quarrel as to whether and how much Cowper had plagiarised from Bidloo. Dr. Beekman discusses the charge with great detail and makes it clear that while Cowper may have been a superior man of science and a more original observer, he none the less made an unfair use of Bidloo's plates, and certainly he put up in defence of his actions a very thin explanation. The question of plagiarism to the ordinary observer would seem to be settled by looking at the title-page to Bidloo's work and the title-page to the work by Cowper; reproductions of these allegorical designs are supplied by Dr. Beekman and no one can doubt that the later one was copied from the earlier.

VITAMIN A IN FISH LIVER OIL

CONFLICTING statements in connexion with halibut liver oil are dealt with in a circular which we have received from the Crookes Laboratories (British Colloids Ltd.), Park Royal, London, N.W. The circular explains the procedure for the accurate determination of vitamin A in oils, and has been written to meet embarrassments of medical men who wish to understand the results of contradictory assays. Taking the standpoint of being pioneers in the field, the circular from the Crookes Laboratories describes the advantages and disadvantages of the different methods now in use for such determination and the reason for adopting a particular one.

The methods described are (1) blue test, (2) spectrographic, (3) vitameter, and (4) biological, and the advantages, disadvantages, and standards of accuracy obtained are set out in tabular form for each method. Since all the methods measure the amount of vitamin A present in the oil, they can be correlated in the case of halibut liver oil, and the relationship between them is shown as follows:

	Per cent. vitamin A	1
(1)	Blue units (C.P. 20 per cent.) ..	800
(2) (3)	$E^{1\text{ per cent.}}_{1\text{ cm.}}$	16
(4)	Biological international growth units	25,000

The circular states that in practice oils are evaluated by either the blue test or the vitameter method with an occasional check by the biological method, but the spectrographic method is held to give greater accuracy—an argument for the replacing by it of the blue or Carr-Price test as far as the Crookes Laboratories are concerned. But the value under the Carr-Price method corresponding to the vitamin content will be quoted from the laboratories for a limited time, future determinations being carried out by, and guarantees being based on, the spectrographic method.

Crookes halibut liver oil is stated to be available in various forms, all of which are issued with a certificate as to vitamin potency. They include collosol halibut liver oil (as drops and capsules). Halimalt, a blend of oil with malt extract and orange juice made palatable for children; Halycitrol, in which glucose takes the place of the malt extract in Halimalt; and Halycalcyne, where calcium phosphate is added to the oil, and regarded as a prophylactic, while indicated in conditions of calcium deficiency.

MEDICAL PIONEERS OF MOTORING

IN a recent obituary notice of Mr. F. W. Ramsay, who died at Bournemouth in his 73rd year, he was described as a pioneer motorist, and a founder member of the Royal Automobile Club. The final instalment in *St. Bartholomew's Hospital Journal* for May of Mr. E. C. O. Jewesbury's entertaining biography of Charles Barrett Lockwood recalls him as another pioneer motorist. Lockwood was the first member of the Bart.'s staff to drive himself to hospital in his own car. The machine was a Panhard with tube-ignition, painted a bright scarlet, and it was a disappointment to students that it was not driven into the hospital square, but always left outside in Smithfield—desirable, no doubt, in view of the disturbance to patients likely to result from the preliminaries to its departure. A delightful picture of this machine, reproduced from a photograph belonging to Sir Archibald Garrod, appears in the article. It was known by students as "The red peril." Mr. Jewesbury tells a story of Lockwood getting into trouble with the police near Chancery Lane, and in consequence arriving late in his ward. "Are there any policemen in here?" he demanded. "Three," he was told, and they were almost ready to go. "Discharge them," he said. Lockwood had the sagacity to see what value the motor-car would be to the medical profession and in 1906 he became chairman of a "committee of medical men who are users of motor-cars."

QUINS

A CORRESPONDENT writes: "The acquisition of speed at any price seems to-day to be the ruling motive; clipped words, and initials as substitutes for titles, or as implying whole conditions or sentiments, not only are frequent in speech but are increasingly appearing in serious literature, a saving of time for speaker, reader, and writer being the common motive. The Dionne quintuplets born in Ontario in the middle of 1934 have received their meed of publicity from you, and I learn from various newspapers that they are alive, and that the record of their activities affords plenty of copy, while they are now referred to as 'The Quins.' We must evidently get used to a new world of abbreviations. It may be necessary to realise that when the mid comes she may assist into the world trips and quads; that the amb takes the pat to the hosp where the surg ops on him; that the doc gives the panpat a scrip which he takes to the chem, who puts the med in a bot and says OK nix to pay. It is all going to be very difficult for those not bred up in modern hurry."

MEDICAL FILMS

DR. BERNARD KAPLAN writes:—Medical men who are amateur cinematographers may be interested to learn that the Institute of Amateur Cinematographers has established a section devoted to medical and allied subjects. The Institute will be pleased to receive films for classification and criticism, and helpful advice will be offered, if desired, on the technical or other aspects of the subject. Where applicable, copies of original films will be made for circulation amongst medical men and medical bodies, and it is hoped that a useful and instructional library may be built up. Foreign workers have intimated their interest in this branch of the Institute's activities, and their observations and pictorial records should be of the utmost value. The films comprising this library will be under the control of a medical man, and due care will be taken of all those entrusted to the Institute. I must emphasise that no charge is made, either for help, or to those interested in the viewing and showing of these films. It is felt that the services offered will ensure that films made by individual workers will receive attention and recognition. Films and communications should be addressed to me, c/o The Institute of Amateur Cinematographers, Burley House, Theobald's-road, London, W.C. 1.

ERRATUM.—*In some of the copies of* THE LANCET *last week the figures in Mr. Green-Armytage's statement on p. 1255, col. 1, that 3 ounces of fresh protein contains 7 grains of calcium were transposed.*

ADDRESSES AND ORIGINAL ARTICLES

LATE RESULTS OF THE OPERATIVE TREATMENT OF OSTEO-ARTHRITIS OF THE HIP-JOINT[*]

Y C. Max Page, D.S.O.; M.S. Lond., F.R.C.S. Eng.

DIRECTOR OF THE SURGICAL UNIT, ST. THOMAS'S HOSPITAL; SURGEON TO VICTORIA HOSPITAL FOR CHILDREN; CONSULTING SURGEON TO METROPOLITAN POLICE

It is only during the past ten years or so that urgery has taken an active part in the treatment f chronic non-tuberculous arthritis, a condition enerally termed in England osteo-arthritis. The process is essentially a chronic one and is induced by various factors by no means always ascertainable. On this account, especially in its early stages, the physician, physicotherapeutist, or often the quack apply different remedies according to their individual convictions in an attempt to control the disease. With the development of asepsis and the stimulus given by radiology—both by its provision of more exact diagnosis of the joint condition and its assistance n the checking of operative procedures, surgery has gradually taken a greater share in treating advanced cases.

In dealing with the disease in its localised form operative measures have achieved a considerable success, but it cannot be said yet that opinion is unanimous as to the methods which should be applied to one of the major weight-bearing joints, the hip. I propose therefore to investigate this problem with the help of the literature and the analysis of a group of some 100 cases upon which I have operated during the past fifteen years.

Pathology

It may be well in the first place to make an attempt to define the nature and development of the various conditions met with in the pathological rubbish heap called chronic arthritis. There is much confusion in the nomenclature of the subject which may be accepted as an index of our ignorance of the exact pathology of the various conditions concerned. The term osteo-arthritis is in this country applied to joint conditions in which the final morbid anatomy is easily recognisable. On the Continent the term arthritis deformans is more often employed in the same sense, and American authors generally classify the condition under the general term chronic non-specific arthritis, subdividing it into proliferative, degenerative, and atrophic groups.

The factors which are recognised as associated with the development of the disease may be tabulated as follows :—

LOCAL CAUSES

1. Previous trauma—old fractures, particularly those involving the articular surface.
2. Nutritional diseases of bone in childhood—Perthes and perhaps slipped epiphysis.
3. Congenital deformities and dislocations.
4. Upsets in the blood-supply to the articular area—osteochondritis dissecans.
5. Subacute infection of the joint.

GENERAL CAUSES

1. Circulation in the blood stream of toxic materials derived from closed septic foci or the intestinal tract.
2. Interference with the nerve-supply to the articular surfaces.

EXPERIMENTAL EVIDENCE

The determining causes which initiate the pathological sequence—partly degenerative and partly proliferative—which lead to the progressive joint changes, are not yet fully understood ; and it must be admitted that many different conditions and processes may lead to joint changes which are indistinguishable in their final form.

Generalising our views on the subject, it may be said that given a hip-joint in which the nutrition of the joint surfaces has been upset by epiphyseal disease, trauma, or infection, some undetermined factor may initiate the slowly progressive changes which we recognise as osteo-arthritis. The factor may be a circulating toxin developed in an infective focus ; it may be some chemical produced as a result of some upset in metabolism or endocrine disturbance.

The ultimate condition of the hip which we classify as osteo-arthritis is characterised by the absorption of the articular cartilage, the secondary sclerosis of the underlying bone associated with the formation of cysts together with marginal hypertrophy. Hypertrophy of the synovial membrane, small-celled infiltration of the capsule of the joint, and fibrosis of the surrounding muscles occur in varying degrees, and it is often impossible to say how far these conditions are secondary to the progressive disintegration of the joint, or how far they represent the first step on the downward path. The changes may be predominantly in one joint and the hip is particularly prone to be the one involved, but a slighter grade of the same condition can generally be observed in other joints in the same patient. In some cases the nervous supply of the joint, either sensory or sympathetic, is at fault. Eloesser[1] has proved experimentally that anæsthesia produced in a limb by the section of the posterior nerve-roots does not itself produce the changes of osteo-arthritis in the affected limbs, but that such changes are initiated by trauma.

I may here refer to *rheumatoid arthritis*, which in its inception is essentially polyarthritic and associated with the phenomena of a subacute infective process. In its typical form it runs its course over several years generally leaving the patient severely crippled. In this final stage the joints may be dealt with surgically, though the multiplicity of the lesions is a great handicap to success. There are borderline cases between this infective condition and osteo-arthritis which are generally classified under the term atrophic arthritis. A certain number of these cases have been operated on and included in the series reviewed later.

Surgical aid in the form of positional treatment and the provision of apparatus for the protection of the joint have their place in quite early stages of the disease. Major operations will usually only be undertaken on the account of the presence of the two clear indications, pain referred to the joint and disabling deformity, either alone or in association. In certain cases—e.g., ankylosis or stiffness of both hips may justify a surgical attempt to restore movement.

Before deciding on the surgical treatment in any individual case, an attempt should be made to localise the source of the pain as it may have considerable influence on the choice of method.

---

[*] A Hunterian lecture delivered before the Royal College of Surgeons of England on Feb. 8th, 1935.

ANALYSIS OF PAIN

The pain of arthritis may be due to irritation of the nerves underlying the articular cartilage. This pain is most in evidence in the early stages of the disease, and I think passes off when the articular cartilage has been completely eroded and the underlying bone has become sclerosed. It would appear that in the stage of erosion of the hip cartilage pain is often referred to the knee. Pain from the joint capsule is present when there is infiltration of the capsule with exudate or stretching of it from progressive displacement of the femoral head. Muscle pain is noticeable when there is much deformity associated with spasm, and is seldom entirely absent till the joint is stabilised either from a termination of active disease or by the immobilisation of the joint. Various degrees of sciatica are common, and in the more severe cases may be due to a definite neuritis. The sciatic pain is, however, usually regarded as due to referred pain from the hip-joint.

It may be noted that the degree of pain is not determinable by reference to the bony deformity. One sees cases of bilateral hypertrophic arthritis of both hips in which one joint is practically painless and the other joint, showing a similar radiogram, acutely painful. Again, capsular or muscular pain may be present in instances in which the joint surfaces are radiologically not far from normal.

In actual practice a clear recognition of the origin of the pain is often only possible by means of trial and error in methods of treatment, but if the evidence is at all clear it may help in deciding what physical or surgical procedure may be most effective in giving relief. It is assumed that physicotherapeutic measures have been tried and proved ineffective before the surgeon is called in. Of these measures the one which has given the most noteworthy results is deep X ray therapy. The application of this agent is fairly recent, and its action in relation to these cases is not understood, but its efficiency in a percentage of cases is striking. Dausset and Lucy [2] quote the results they have obtained in 50 cases and state a definite improvement was observed in half of the patients treated, and that the improvement continued for periods up to two years. They are not able to define the joint conditions which determine the success or failure of the method. Watt [3] reports an even higher percentage of satisfactory results from this method of treatment in early cases of arthritis. His conclusions are not based only on hip-joint, but he states that the results in long-standing cases are less satisfactory.

DEFORMITY

The deformity constantly observed in this disease is flexion and adduction of the thigh. It may be caused by muscle spasm, but occasionally is assisted in its development by subluxation of the joint. Secondary lordosis and lateral curve of the spine are produced when the patient assumes the erect attitude. The strain so imposed on the sacro-iliac and lumbar spine joints may be the source of pain apart from any arthritic change in these joints.

Surgical Methods

I will now consider the various types of surgical treatment which are at present in vogue.

Procedures directed to correct malposition of the joint, which develops in the course of the disease and which may be the source of pain as well as disability, may be referred to as coming under the classification of surgical treatment. Under this heading come manipulation of the joint and stretching of the adductors, associated or not with section of their tendons. The limb is then immobilised in plaster for a month or so in the corrected position. Subsequently a weight-relieving calliper may be worn for a few months in order to prevent recurrence of the deformity and as far as possible to save wear and tear of the joint surfaces. The length of time the calliper is worn will usually be determined by the patient, in as far as he finds the relief afforded outweighs the encumbrance of the apparatus.

In Scandinavia Camitz [4] is an advocate of this type of treatment, and he effectually prevents recurrence of adductor deformity by resecting the obturator nerve and part of the pectineus muscle on the affected side. He advocates subsequent fixation for only two weeks and follows this up with a long course of physicotherapeutic treatment.

In describing his method he gives details of 7 out of 50 cases operated on during the last ten years, in most of which satisfactory relief of pain and return of function were obtained.

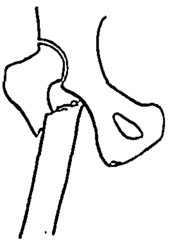

FIG. 1.—Tracing of radiogram after bifurcation osteotomy of femur (after Hass).

Osteotomy of the neck of the femur is based on the similar idea, that of restoring the natural line of stress to a deformed joint. A simple subtrochanteric osteotomy may be practised or the bifurcative operation (Shanz, Lorenz) carried out. The latter procedure aims at more than reposition of the limb, as by abutting the cut lower end of the femur on the subacetabular rim weight is no longer passed through the hip-joint. (Fig. 1.) Hass [5] is a strong advocate of this latter measure.

The first recorded radical surgical attack on the hip, the seat of osteo-arthritis, was by an excision of the head carried out by H. Foch [6] in 1857. Though further isolated attempts at surgical treatment are recorded, it was not until Albee [7] introduced his arthrodesing operation in 1908 that any material progress was registered in attacking the problem by surgical methods. Albee has used his method in a large number of cases. He later introduced the use of a bone graft in order to secure bony fusion with greater certainty. He is well satisfied with arthrodesis carried out by his methods and has operated on a large number of cases; detailed reports of late results do not appear to be available.

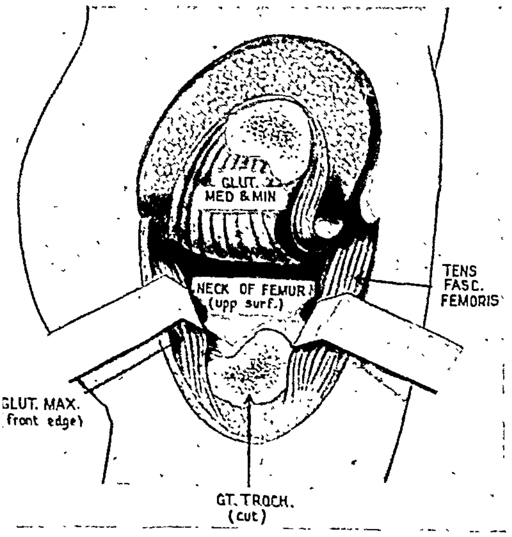
Whitman [8] advocated his reconstruction operation for the relief of the condition in 1925; the aim of this procedure is to obtain a movable joint after removing as far as possible abnormal bone. He pins his faith to this operation for the condition in question.

To judge by the literature, the last five years has seen a great increase in the surgical interest in the treatment of osteo-arthritis of the hip in France. In addition to arthrodesing operations and arthroplastic resections the buttress operation of Lance seems to have gained a considerable vogue. It consists in the establishment of a bony block above the joint to prevent progressive dislocation. The application of this operation would appear to be limited to cases in which subluxation is the prominent factor. It does not attack the joint surfaces and so cannot be expected to bring the disease process to an end.

Another operation of Gallic origin is the recently introduced "forage du col," by Duvernay and tson-Lavalle.[9] The procedure was founded idea that the nutrition of the head of the femur ourably influenced by driving a bone graft into bstance. A track is drilled through the great nter into the neck and head of the bone without ng the joint. Some authors drive a graft the track; others do not. The method has on trial for only a few years, and it is therefore ture to pass any judgment on it. On the f it, it would not seem likely to be more than orarily effective, whatever the basis of its action. ts on the value of "forage du col" are made vernay,[9] Rocher,[10] Arnaud and Cleret.[11] They ll favourably impressed by the method, but only a few recent cases.

eo and Rocher[11] surveyed the whole subject 32 without formulating any conclusions at the first Congress of the French Association of ons. Mathieu[12] gives a good account of the al position and quotes the results of 18 cases d in various ways. He states that of 8 attempted oplasties the results were good in 6 and unsatis- ry in 2. Tavernier,[11] after a trial of arthro- c resection in 8 cases, concludes that arthrodesis be preferred to any other form of surgical treat- . Roederer and Graffin[13] reserve arthrodesis xceptional cases and are impressed by the rtance and value of positional treatment after tomy. The buttress operation is reported on asmonteil[11] and others, but the consensus of on seems to limit the application to old cases bluxation of the joint.

att[14] discusses the relative value of resection the head and arthrodesis without any detail of material. He prefers an arthrodesis carried through a Murphy approach.



. 2.—Schematic drawing of Murphy approach to the hip-int, employed in 76 cases. Glut.=glutoreus muscles. Tens. sc. fem.=tensor fasciæ femoris. Gt. troch.=great trochanter.

he most recent English figures are reported by Bristow[15] who in an analysis of 67 cases rated on for osteo-arthritis compares the merits he reconstructive type of operation with arthro- is. He analyses the results of 33 cases in which e form of arthrodesis was aimed at and of 34 rations for arthroplastic reconstruction. His clusions favour arthrodesis for young to middle-aged patients in whom only one hip-joint is involved; he would reserve the attempt at arthroplasty for those in whom both hips or their major joints are involved, or for the aged.

The views of German surgeons are perhaps expressed by Burckhardt[16] in a painstaking compilation in the new German Surgery on Arthritis Deformans. He does not favour arthrodesis, but considers that more satisfactory results are obtained by one of the various remodelling operations.

Payr[17] considers the outlook in plastic operations on the hip good and states that 60 to 70 per cent. of these operations are successful. In old patients he prefers a saddle or bifurcation osteotomy. He seems to be impressed by the disadvantages of an arthrodesis and with the severity of the operation necessary to gain this end. He emphasises the importance of a mobile spine if an arthrodesis is to be satisfactory.

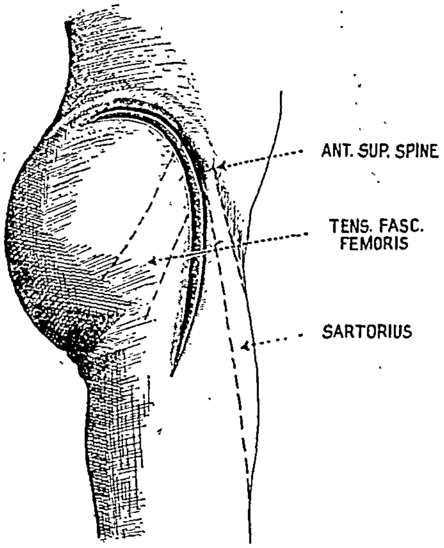


FIG. 3.—Diagram of skin incision for Smith Petersen approach to hip-joint.

Bergman[18] records a follow-up of Hildebrand's cases—the only late investigation of any weight which I can find in the German literature. A reconstruction operation had been carried out in all. Three deaths were attributed to the operation. Sixty cases had been operated on in 15 years, mostly aged between 40 and 60.

Of 11 cases reporting 4 were well pleased with the result, 5 said they were worse since the operation. Two of these latter cases were aged 24 and 32.

Of 17 examined 13 were improved and 4 unaltered or worse.

Among the 13 satisfactory cases the functional value of the hip-joint was as follows:—

Bony ankylosis	2
Slight movement	3
Useful movement	8

He states in conclusion that he prefers an arthrodesis for heavy weight-bearers, but prefers arthroplasty for others.

Analysis of Author's Cases

I will now turn to my own experience. During the past fifteen years I have operated on 112 cases for chronic non-tuberculous arthritis of the hip-joint. I propose to consider the late results of these operations. I have limited my investigation to the results of the two radical operations—viz., attempts at arthrodesis, attempts at arthroplasty. All the cases in the series had been subjected to longer or shorter courses of physicotherapy, and many to minor surgical interventions before radical operation was undertaken, but I am not in a position to consider the results of these procedures. Seventeen cases have been operated on since July, 1932, and I have considered the intervening period too short to render

ANALYSIS OF PAIN

The pain of arthritis may be due to irritation of the nerves underlying the articular cartilage. This pain is most in evidence in the early stages of the disease, and I think passes off when the articular cartilage has been completely eroded and the underlying bone has become sclerosed. It would appear that in the stage of erosion of the hip cartilage pain is often referred to the knee. Pain from the joint capsule is present when there is infiltration of the capsule with exudate or stretching of it from progressive displacement of the femoral head. Muscle pain is noticeable when there is much deformity associated with spasm, and is seldom entirely absent till the joint is stabilised either from a termination of active disease or by the immobilisation of the joint. Various degrees of sciatica are common, and in the more severe cases may be due to a definite neuritis. The sciatic pain is, however, usually regarded as due to referred pain from the hip-joint.

It may be noted that the degree of pain is not determinable by reference to the bony deformity. One sees cases of bilateral hypertrophic arthritis of both hips in which one joint is practically painless and the other joint, showing a similar radiogram, acutely painful. Again, capsular or muscular pain may be present in instances in which the joint surfaces are radiologically not far from normal.

In actual practice a clear recognition of the origin of the pain is often only possible by means of trial and error in methods of treatment, but if the evidence is at all clear it may help in deciding what physical or surgical procedure may be most effective in giving relief. It is assumed that physicotherapeutic measures have been tried and proved ineffective before the surgeon is called in. Of these measures the one which has given the most noteworthy results is deep X ray therapy. The application of this agent is fairly recent, and its action in relation to these cases is not understood, but its efficiency in a percentage of cases is striking. Dausset and Lucy [2] quote the results they have obtained in 50 cases and state a definite improvement was observed in half of the patients treated, and that the improvement continued for periods up to two years. They are not able to define the joint conditions which determine the success or failure of the method. Watt [3] reports an even higher percentage of satisfactory results from this method of treatment in early cases of arthritis. His conclusions are not based only on hip-joint, but he states that the results in longstanding cases are less satisfactory.

DEFORMITY

The deformity constantly observed in this disease is flexion and adduction of the thigh. It may be caused by muscle spasm, but occasionally is assisted in its development by subluxation of the joint. Secondary lordosis and lateral curve of the spine are produced when the patient assumes the erect attitude. The strain so imposed on the sacro-iliac and lumbar spine joints may be the source of pain apart from any arthritic change in these joints.

Surgical Methods

I will now consider the various types of surgical treatment which are at present in vogue.

Procedures directed to correct malposition of the joint, which develops in the course of the disease and which may be the source of pain as well as disability, may be referred to as coming under the classification of surgical treatment. Under this heading come manipulation of the joint and stretching of the adductors, associated or not with section of their tendons. The limb is then immobilised in plaster for a month or so in the corrected position. Subsequently a weight-relieving calliper may be worn for a few months in order to prevent recurrence of the deformity and as far as possible to save wear and tear of the joint surfaces. The length of time the calliper is worn will usually be determined by the patient, in as far as he finds the relief afforded outweighs the encumbrance of the apparatus.

In Scandinavia Camitz [4] is an advocate of this type of treatment, and he effectually prevents recurrence of adductor deformity by resecting the obturator nerve and part of the pectineus muscle on the affected side. He advocates subsequent fixation for only two weeks and follows this up with a long course of physicotherapeutic treatment.

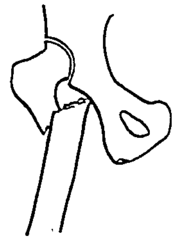

FIG. 1.—Tracing of radiogram after bifurcation osteotomy of femur (after Hass).

In describing his method he gives details of 7 out of 50 cases operated on during the last ten years, in most of which satisfactory relief of pain and return of function were obtained.

Osteotomy of the neck of the femur is based on the similar idea, that of restoring the natural line of stress to a deformed joint. A simple subtrochanteric osteotomy may be practised or the bifurcative operation (Shanz, Lorenz) carried out. The latter procedure aims at more than reposition of the limb, as by abutting the cut lower end of the femur on the subacetabular rim weight is no longer passed through the hip-joint. (Fig. 1.) Hass [5] is a strong advocate of this latter measure.

The first recorded radical surgical attack on the hip, the seat of osteo-arthritis, was by an excision of the head carried out by H. Foch [6] in 1857. Though further isolated attempts at surgical treatment are recorded, it was not until Albee [7] introduced his arthrodesing operation in 1908 that any material progress was registered in attacking the problem by surgical methods. Albee has used his method in a large number of cases. He later introduced the use of a bone graft in order to secure bony fusion with greater certainty. He is well satisfied with arthrodesis carried out by his methods and has operated on a large number of cases; detailed reports of late results do not appear to be available.

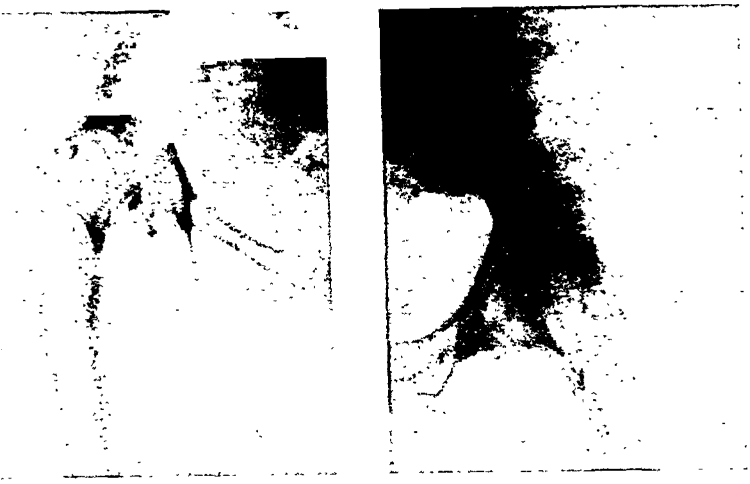
Whitman [8] advocated his reconstruction operation for the relief of the condition in 1925; the aim of this procedure is to obtain a movable joint after removing as far as possible abnormal bone. He pins his faith to this operation for the condition in question.

To judge by the literature, the last five years has seen a great increase in the surgical interest in the treatment of osteo-arthritis of the hip in France. In addition to arthrodesing operations and arthroplastic resections the buttress operation of Lance seems to have gained a considerable vogue. It consists in the establishment of a bony block above the joint to prevent progressive dislocation. The application of this operation would appear to be limited to cases in which subluxation is the prominent factor. It does not attack the joint surfaces and so cannot be expected to bring the disease process to an end.

Another operation of Gallic origin is the recently introduced "forage du col," by Duvernay and ro- deaths occurred while the patients in this s were in hospital. The details are as follows :—

se 1.—A man, aged 73, died of cellulitis of the wound h in itself was not very serious. At the post-mortem patient was found to have evidence of prostatic uction with a trabeculated bladder and small fibrous eys, and the cause of death was almost certainly nia. The blood-urea was not estimated before ation.

se 2.—A man, aged 69, who died shortly after operation at the post-mortem was found to have meningitis. uring life he developed post-operatively the clinical signs tetanus, but the diagnosis was never definitely tablished.



FIGS. 5 and 6.—Radiograms showing sound bony ankylosis.

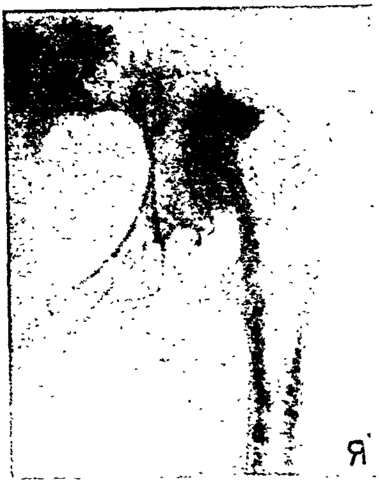


FIG. 7.—Radiograms showing fibrous joint and subluxation.

Age and sex of patients.—The average age of the atients operated on was 51 years. The oldest atient was 73 and the youngest 21. There were 3 males (13 army pensioners) and 33 females.

Complications during convalescence.—Pressure sores om the plaster spica were troublesome in a few cases nd sometimes have necessitated the use of a skeleton plint in place of the plaster. Wound hæmatoma as recorded in eight. With careful hæmostasis his should not occur, and I do not think drainage f these wounds is called for. The complication as been less frequent in my later cases since outine ligature of all bleeding points has been arried out. Bleeding from the bone in arthrodesis operations is not usually troublesome, but may be persistent.

Suppuration.—Secondary superficial suppuration in the posterior sector of the Murphy incision is common (ten cases). It does not interfere with the course of treatment. It is not common with a Smith Petersen incision. Deep suppuration is recorded in two cases and, as might be expected from the extent of the wound, is a serious matter. It necessitates transferring the patient to a skeleton splint. This makes positional control difficult. In one case (Case 94) an erysipelas developing three weeks after operation from a hæmatoma sinus led to a mild pyæmic state from which the patient was lucky to escape with his life.

Deep venous thrombosis is recorded nine times. It most often appeared in the left leg whichever side was operated on. It has not, as a rule, interfered with positional treatment, but it impedes the functional return of power in the limb and tends to intensify the post-operative stiffness of the knee on the affected side.

There was no case of severe pulmonary embolism in this series. One case with transient effects is recorded (Case 59).

Chest complications.—In opposition to the generally accepted idea that the elderly patient immobilised in plaster is particularly liable to bronchitis and hypostatic pneumonia this series does not confirm that view. No serious instance of pulmonary complications is recorded. It should be noted that a high plaster spica was never used.

Mental complications.—In the middle aged the shock of a big operation followed the sense of helplessness involved by plaster or splint fixation not infrequently leads to some mental upset. Most patients if put in the open and given reasonable doses of alcohol recover their equanimity in a few days. Four cases of mental trouble sufficiently severe to interfere with routine treatment are recorded in this series, but no patient was transferred to a mental hospital.

Interval between operation and restoration of function.—The time taken before the patient derives the maximum benefit varies in individual cases; for instance, there are men in this series who were back at work within eight months of operation and whose hips have stood the test of time very well indeed; there are others who state that they did not really settle down after operation for two years or more. There is no doubt that, provided the operation had relieved the pain, a patient who is able to coöperate will get walking and improve very much more rapidly than one in whom the "spirit is weak." In this connexion it is striking that several of the patients state that they did not really get going until they were discharged from the massage department and until they started to get about in their own homes. It seems therefore that the efforts in the massage and electrical departments should be devoted to overcoming the stiffness in the other joints, especially in the knee on the side of the operation, which stiffness occurs as the result of prolonged fixation in plaster, and also to establishing the efficiency of the muscles around the hip, since these muscles are usually wasted and atrophied, and consequently are inadequate to control the balance of the body, even in the end-results of any value, and so they have not been included in the Table.

An exact definition of the nature of the joint changes in the group investigated is not possible. Nearly all cases were advanced examples of osteo-arthritis and, as has been pointed out above, the recognisable pathology in the final state is the same whatever factors may have initiated the primary change. In the table giving details of the individual case it is stated whether the condition for which operation was undertaken was a hypertrophied or atrophic arthritis, and whether subluxation was present and how far the disease was monarticular.

The approach to the hip-joint employed in each case is stated in the main table. One of two recognised approaches have generally been used—viz., either based on Murphy's method (76 cases) or on the Smith Petersen[19] (15 cases). Irregular approaches were used five times. The Murphy approach has been employed exclusively when a reconstructive operation was carried out. The vertical part of this incision has only been made when the great trochanter has been planted below its normal situation. The approaches are sufficiently well known to render it unnecessary to describe them in detail. The Figs. 2, 3, and 4 delineate their essential features.

OPERATIONS AIMING AT ARTHRODESIS

In attempting an arthrodesis the joint has normally been dislocated—posteriorly after the Murphy approach, anteriorly after the Smith Petersen. The surface of the head of the femur has then been cut away till a shaped head of apparently healthy and vascular bone is left. The upper sector of the acetabular roof is next cut away with a large gouge. This is the only difficult part of the operation; it is by no means easy to expose well the vascularised bone in the acetabulum without destroying the shape of the cavity. The head of the femur is then replaced in the socket, a formal extra-articular iliac graft is only used exceptionally. The great trochanter is fixed back in place by suture or a fine wire nail, and the wound resutured.

After-treatment.—The patient is fixed in a plaster-of-Paris spica with the thigh in the position in which fixation is desired. This is usually 25 per cent. flexed, slightly abducted, and externally rotated. Tenotomy of the adductors is carried out if spasm opposes the maintenance of this position. The plaster spica has not been extended to the chest. It relies for control of pelvic movement upon its extension to the upper half of the sound thigh with a well-defined grip of the tuber ischii on the sound side. In old patients I am sure that this type of spica is better tolerated than one fixing the lower part of the chest and so enforcing complete recumbency. The spica is maintained in position for about two and a half months. The plaster is often changed about three weeks after operation. Two to three months after operation a short spica is applied and the patient started to walk with crutches. Patients are left free of any splint not later than the fourth month, after which general physicotherapeutic measures are applied to restore function and mobility of the normal joints.

OPERATIONS AIMING AT A MOBILE JOINT

After exposing the joint by the Murphy route the head is dislocated backwards. The ileo-femoral ligament is thus left intact. The head of the femur is cut off and the stump pared down so as to leave a rounded end of healthy bone which fits the acetabulum loosely. The acetabulum is not touched. Free fascia has been used in a few cases to cap the bone, but latterly I have limited myself to waxing the raw surface of the femoral neck. After replacement of the stump in the acetabulum the great trochanter is pinned back on the shaft of the femur about 1 in. below its original situation on to a prepared raw bone bed. This operation can be performed with sufficient precision in about twenty minutes.

After-treatment.—Many cases have been fixed in a plaster spica for two or three weeks after operation as it has been found easier to nurse them when so fixed. At the end of the period they are transferred to a Hodgen splint to which, weight traction of 5 to 10 lb. is applied for a few weeks. After this the patient usually lies free in bed, and is encouraged to move the hip passively with the help of a sling and pulley.

A weight-relieving calliper is sometimes fitted for a few months at about eight weeks after operation. In any case weight-bearing is not allowed till three to four months after operation. Physicotherapeutic treatment is employed about a month after operation.

Results

Ninety-six cases have been investigated for me by my chief assistant, Mr. N. R. Barrett. Nineteen cases were operated on at a Pensions Hospital and have not been followed further than when reported on by me in 1924.[20] The others, with the exception of six who could not be traced, have answered a questionnaire or have been examined by N. R. B. and X rayed during the past year. The figures showing the time after operation at which the cases have been examined are:—

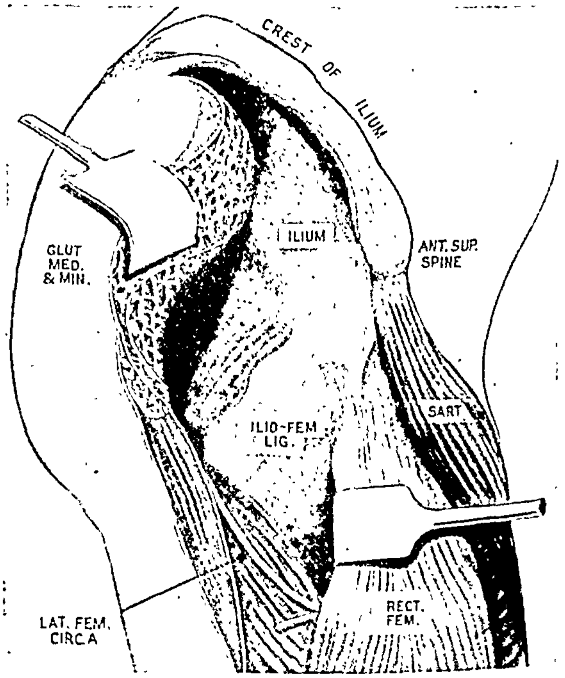

FIG. 4.—Schematic drawing of exposure of the hip-joint by Smith Petersen method, employed in 15 cases. Ilio-fem. lig. = ilio-femoral ligament. Rect. fem. = rectus femoris muscle. Lat. fem. circ. A. = lateral femoral circumflex artery.

Under five years	36 cases.
Over five years and up to fourteen ..	53 ,,

Case No.	Age and sex.	Side	Condition and ætiology.	Operation and approach.	After treatment.	Movement possible in the joint and/or condition of joint by X ray when last seen.	Position and shortening. (*b*) Pain in R. knee. Condition in this knee has not changed since before op. Also has arthritis of lumbar spine, but does not complain of this.	(*c*) Good; can walk about easily and do household work. (*d*) Excellent.	10 y.
62	59 M.	R. and L.	Pain in both hips and L. shoulder, 4 years. X ray: Hypertrophic O.A. both hips.	19/2/27: Removal of diseased cartilage and remodelling of femoral head. Acetabulum not touched. Murphy approach. L. hip.	Treated on a Hodgen splint.	State to-day: L. hip: Some movement possible in all directions, limited by pain. R. hip: Painless and fixed.	Some adduction and flexion. ½″ short.	(*a*) Yes. (*b*) None.	(*c*) Poor result; op. has resulted in a painful arthroplasty. (*d*) Op. definitely worth while.	7 y.
65	64 F.	L.	2½ years' of pain in L. hip. Recently similar pains in the other hip and both knees. X ray: O.A. hip, but not of other joints.	16/2/27: Erasion of joint after dislocation. Murphy approach.	P.P.S. 9 weeks.	X ray 1934: L. hip: Very marked beak of bone above the femoral head. Joint space present. Sclerosis ++. R. hip: Similar condition on other side. Not so advanced. Unsound arthroplasty.	Good position. 1″ short.	(*a*) Hip very painful on movement. Movements limited by spasm. (*b*) Spine, R. hip, knees, all painful.	(*c*) Bad result; limited to some extent in movements; foot drop which still remains. (*d*) Op. no good.	7 y.
74	55 M.	R. and L.	Pain and stiffness in both hips for 1 year. X ray: Advanced O.A. of both hips. R.>L.	23/7/29: Whitman's reconstruction of hip on R. side. Murphy approach.	P.P.S. for a few weeks; replaced by Hodgen splint and extension after suppuration.	X ray 1934: R. side: Joint space present. Sclerosis on either side of the joint. New bone laid down in a beak above the neck. L. side: Advanced O.A. with new bone above the neck. Painless pseudarthrosis on side of op. About 25° of flexion possible.	Good position. 1½″ short.	(*a*) None. (*b*) Pain continues in the *other* hip, but X ray does not suggest that bone changes have progressed since op.	(*c*) Excellent on the side of op.; result limited by other hip. (*d*) Op. a success.	5 y.
76	49 F.	R. and L.	9 years' pain and stiffness in both hips. X ray: Hypertrophic O.A. of both hips.	27/2/29: Removal of osteophytes and cartilage from head of femur. Acetabulum not touched. Murphy approach. L. hip.	Thomas's splint with extension by a pin through the os calcis.	Painless pseudarthrosis on L. side. Not much movement possible.	Both sides in good position. About 2″ short on each side.	(*a*) None. (*b*) Both knees stiff and occasionally painful.	(*c*) Moderate. Pain cured but patient cannot get about much, as movement at hips is not sufficiently free. (*d*) Ops. worth while, but disappointed that she cannot get about much.	5 y.
				20/12/29: Same operation as above. Murphy approach. R. hip.	Treatment as above.	Painless pseudarthrosis on R. side. Very little movement. Has some rotary control on this side.				
83	53 F.	R. and L.	22 years' history of O.A. both hips. X rays: Marked O.A. clinically. R. hip painful, L. hip practically fixed.	15/3/30: Head of femur trimmed up. Fascial covering inserted around the head. Murphy approach.	Pearson bed with 7 lb. extension.	X ray 1934: R. hip: Head of femur missing, broad joint space. Sclerosis ++. Sound arthroplasty. L. hip: Typical appearance of old O.A. with beak of bone above the femoral neck.	Good position. Not much shortening.	(*a*) None. (*b*) Pain in other hip occasionally.	(*c*) Moderate. Condition of other hip spoils functional value of op. (*d*) Op. well worth while.	4 y.

In the above Table, Cases 38, 44, 45, 62, 65, 74, 76 and 83 are referred to in the text. The table, which was worked out in order to investigate 96 cases, will be published in full in the 1935 edition of the St. Thomas's Hospital reports.

patients where the hip condition is absolutely satisfactory.

ESTIMATE OF LATE RESULTS IN TRACED CASES

Results are divided into good, moderate, and bad. The *good* results are those who clinically are good walkers, without pain elsewhere, and who have been able to get about almost as well as normal individuals. The *moderate* results are those whose local condition is absolutely satisfactory but in whom the result has been spoilt by pain elsewhere, or by some late complication directly connected with the operation; practically everyone of the patients in this series has volunteered the opinion that in spite of the severity of the operation and the long convalescence the operation was worth while. The *bad* results are those who have not been improved at all or who are now worse than before operation.

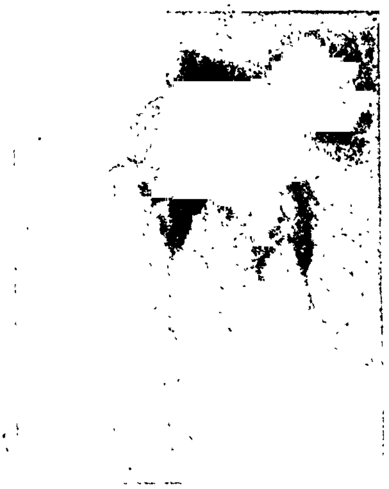

FIG. 8.—Radiogram showing condition when a fibrous joint was present with "beak" formation above the acetabulum.

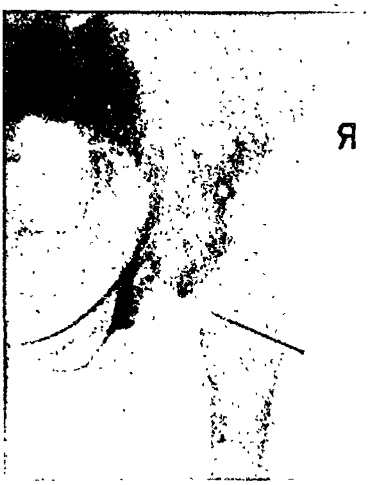

FIG. 9.—Radiogram showing condition three months after arthroplastic resection.

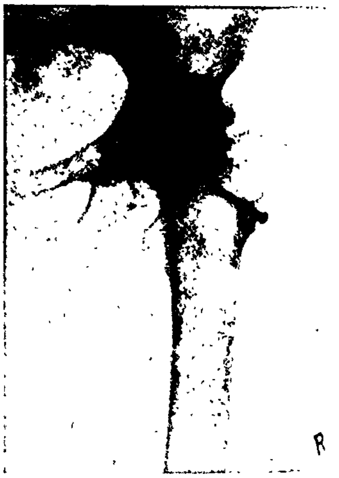

FIG. 10.—Radiogram showing condition four years after arthroplastic resection.

RELATIVE VALUE OF THE TWO TYPES OF OPERATION

Arthrodesis has given better results than arthroplasty. It may be noted that in the 69 cases in which a fixed joint was aimed at this was only obtained in 46 cases. In 29 cases checked by X rays true bony ankylosis was only present in 7. The results of these 46 cases are classified as good or moderate with no complete failures. The total of 14 bad results (after either type of operation) all had movable joints. There may be reasons which make the provision of a fixed joint undesirable or impossible, but it seems to me that there is no doubt that the fixed joint is most certain to give sure and lasting success. Operations for bilateral hip disease have proved disappointing (Cases 44 and 65), though the patient may be pleased with the result (Cases 74, 76, 83).

Operations (69) *aiming at Arthrodesis*

—	Good.	Moderate.	Bad.
Bony ankylosis proved by X rays	7	—	—
Fibrous ankylosis proved by X rays	18	4	—
Clinical ankylosis (X rays not available after operation) ..	13	4	—
Movable joint	11	4	8
Totals	49 (70 %)	12 (17·4 %)	8 (11·6 %)

See Figs. 5, 6, 7, and 8.

Operations (19) *aiming at Arthroplasty*

Movable joint	6	4	6
Fixed joint—			
Fibrous ankylosis	1	1	0
Bony ankylosis	—	1	—
Totals	7 (37 %)	6 (31·6 %)	6

See Figs. 9 and 10.

It may be noted here that these authorities who advocate a reconstruction operation do not claim more than about 60 per cent. of successes (Bergmann and Payr). It must be admitted that the successful arthroplasty gives a brilliant result which surpasses in functional value that of the fixed hip, but in operations for the condition under review these bright spots are too few and far between.

It may be suggested that with a different technique better results may be obtained. I think this is true of the operations arriving at an arthrodesis, but I am very doubtful whether the same can be said of the reconstructive operations aiming at a movable joint. In my experience, which is confirmed by an analysis of these cases and a study of the literature, it is very difficult to say what technical feature of the operation has produced a good result in any given instance. The most ingenious procedures precisely carried out may result in a stiff or painful hip. A rough reconstructive excision may produce a freely movable joint. I think the fate of these cases depends on the vascular supply of the part and the continued activity or otherwise of those factors which were responsible for the primary bone change.

In the case of an operation to produce arthrodesis of the hip-joint we know that quite apart from after-fixation it is a difficult joint in which to procure bony fusion by a simple rawing of the adjacent articular surfaces of the femur and acetabulum. The addition of an extra-articular graft as first advocated by Albee, adds greatly to the chances of success. If I had employed this technique as a routine my technical and probably clinical successes would have been greater in number. At the same time it should be remembered that the effective cutting and placing of an extra-articular graft in the hip takes time, adds to the shock of the operation, and so the likelihood of influenza in January. There was complete absence of abdominal tenderness or rigidity. Rectal examination was negative. Agglutination tests for all the common and uncommon food poisoning organisms had already been carried out and were negative, as was also bacteriological examination of the urine. The white count, however, showed 11,000 leucocytes of which 80 per cent. were polymorphs.

Here I must interrupt the history to suggest that enumeration of the white cells is the second investigation of importance in cryptic fever. A leucocytosis with relative and absolute increase of polymorphs at once excludes a large number of causes of obscure fever—e.g., typhoid, paratyphoid, tuberculosis (except occasionally the miliary form), influenza, and malaria. It strongly suggests that one is faced with a hidden area of inflammation due to one of the common pyogenic microbes. It demands daily meticulous examination if a serious outcome is to be averted. Incidentally, leukæmia as a cause of fever may be revealed by the white count only. In the case quoted, the history was all important because the only symptoms, apart from feverishness, were, though vague, yet definitely abdominal. The fresh rise of temperature after taking castor oil again suggests the alimentary tract as the origin of the trouble.

The next day a further complete examination was carried out, and on this occasion a thickening and tenderness could be detected on high rectal examination. In short, the case was simply one of a "pelvic appendicitis" starting with septicæmic symptoms, subsiding, and then relapsing with abscess formation. The history and the white count indicated approximately the seat and type of the inflammation, and consequently gave rise to sufficient apprehension to demand repeated comprehensive examinations until some sign should turn up to settle the diagnosis.

Rectal examination might be added as the third imperative investigation in pyrexia of unknown origin, particularly if there are associated symptoms of abdominal discomfort or diarrhœa. It is often noticed when a pelvic abscess is present that the anus is peculiarly patulous owing to paralysis of the internal sphincter. An abscess in the prostate may be completely overlooked as the cause of fever if this examination be omitted.

Classification

As a somewhat broad classification of perplexing fevers I suggest (1) endocrine, (2) toxic, (3) cerebral, (4) microbial, the last being much the commonest.

ENDOCRINE ORIGIN

The thyroid is the only member of this group which at all frequently gives rise to slight, but persistent, pyrexia without obvious signs. Early Graves's disease in this way resembles chorea, that once it is thought of it can be diagnosed without difficulty. That is to say, its characteristic signs can be *elicited*. But it is not, perhaps, generally recognised that for several months the disease may be accompanied only by a raised temperature—e.g., 99°, trivial loss of weight, and nervousness without tachycardia or appreciable thyroid enlargement. The startled, wide-open eyes may be noticed for a moment as the patient enters the room, and are not revealed again during the consultation. Rise of pulse-rate on slight exertion and tremor can, however, usually be brought out if looked for.

Occasional outbreaks of fever in the grossly obese are puzzling, and suggest a spasmodic effort of the body to consume its strangling deposits. They disappear with reduction of weight.

TOXIC ORIGIN

Under this heading I include a not uncommon cause of pyrexia, namely, degenerating new growths, e.g., fibroids, sarcomata, and carcinomatous metastases in the liver. In the case of malignant growths the patient always looks ill by the time fever is produced, but often one is hard put to it to clinch the diagnosis.

The prolonged though slight fever which so often follows cardiac infarction is presumably another example of the chemical agency of dead tissue. In the days before the clinical picture had been differentiated from that of angina pectoris, the low grade pyrexia was a fruitful source of worry to many of us, though we must be grateful to it in retrospect for having, by its existence, secured for the patient a prolonged rest in bed.

Alcoholic hepatitis is another example of this group. The instances I have encountered have been in stockbrokers or doctors. In no case could the patient be described as a drunkard, yet the daily consumption of whisky, sherry, and often cocktails has amounted to the equivalent of 150 to 300 c.cm. of alcohol. The liver is slightly enlarged and tender; the evening temperature rises to about 99° F. The pyrexia and liver enlargement may disappear after a few weeks of abstention.

The sale of certain "slimming" drugs, notably dinitro-ortho-cresol is, it is to be hoped, to be severely restricted, otherwise these will also provide us with diagnostic difficulties.

CEREBRAL ORIGIN

I am chiefly concerned here with the psychic functions of the brain, leaving the organic disturbances of the thermotaxic centre, as by heat-stroke, hæmorrhage, or tumour, out of consideration owing to their rarity in the absence of some clear history or sign to indicate the nature of the disease. When, however, we come to the "functional" pyrexias we at once enter a large field. My experience is that the vast majority are factitious, but undoubtedly a few are genuine enough, and occur in very nervous subjects. Children who have had much illness are extraordinarily liable to run persistent fever after, for instance, a simple coryza. It may be argued that this is really evidence of poor resistance to infection, but the fact remains that if they be got up and sent about their ordinary life the fever commonly abates in the course of a day. I have seen a steady pyrexial swing of 98° to 99·2° develop in a neurotic woman after she was diagnosed by an Abrams's box expert as suffering from "streptococci." It lasted five weeks and was said to be cured by percussion of the seventh cervical spine by a chiropractor.

The tricks for the production of pyrexia by the malingerer are legion, most of them being ingenuous. Fortunately, these patients often reveal themselves by feigning extreme exhaustion. They lie prostrate and supposedly semi-stuporose. One's suspicions are aroused by the sight of a well-nourished woman with normal pulse, no physical signs of disease, obstinately closed eyes, and a temperature chart showing fever of several weeks' duration. In every case of this sort the doctor should take the rectal temperature himself, and keep his hand on the thermometer the whole time. If the patient is protecting herself with a semblance of lethargy or semi-consciousness, it often pays to whisper to the attendant nurse. I have not yet met an hysterical or malingering subject whose curiosity could resist such a bait. One notices the head turn ever so of post-operative complications. It is sound business in the healthy patient, but I do not think it should be blindly used in less satisfactory risks.

In the results it will be noted that a large number of the patients are left with the limb in an adducted position. I think a more frequent use of tenotomy of the adductors might lead to an improvement in this respect. The use of a Smith Petersen pin to fix the bones after preparing their surfaces is attractive in theory. In practice it is not easy to drive the pin into the iliac buttress. If the pin merely penetrates the central part of the acetabulum its mechanical value is slight.

DISADVANTAGES OF A FIXED HIP

A hip fixed in a good position is little handicap to a patient in the upright position. They can walk with little limp and can carry heavy weights. The comfortable assumption of a sitting posture is dependent on the mobility of the lumbar spine and knee-joint. If both are free the patient can put on his own shoes and stockings but not otherwise. If there is any degree of fixed adduction the condition may be an impediment to normal sexual life in younger women.

A stiff hip implies secondary strain on the knee, sacro-iliac, and lumbar spinal joints. The knee may develop a measure of hyper-extension. The strain in the lumbar area is often responsible for muscular pain in the early convalescent period. In this group of cases it has seldom been persistent. The presence of early osteo-arthritis in other joints does not entirely contra-indicate radical operation on the hip. Cases 38, 45, and 62 illustrate this point. I think the more chronic the disease in the hip the less probable is secondary changes in other joints. When the process is relatively recent and active in several joints it is advisable to defer radical operation.

The advantages of a successful arthroplasty are obvious from the point of view of general convenience. These patients, however, seldom walk without a dropping limp and are not as physically efficient in the upright attitude as the patient with one stiff hip. The freedom of movement obtained is seldom more than 90° of flexion and 15° of abduction.

It would appear from these results that when the disease is limited to one hip-joint and if the physical condition is sound arthrodesis is the operation of choice. A Smith Petersen incision and the application of an iliac graft will be most likely to give the desired result.

When both hips are involved or if the lumbar spine is stiff and the seat of arthritis a remodelling operation should be chosen. The Murphy approach is satisfactory for this purpose. The speed with which this operation can be carried out and the relatively short period of fixation which is required afterwards make it the operation of choice for elderly patients who are bad risks yet in whom intractable pain justifies operation.

In conclusion I think, though I may have suggested that radical surgery applied to osteo-arthritis of the hip is a somewhat laborious affair for the surgeon and certainly a trial of fortitude to the patient; yet the late results are much more consistently satisfactory to the sufferer than one might expect, and fully justify our enterprise.

PYREXIA OF OBSCURE ORIGIN*

By A. H. Douthwaite, M.D., F.R.C.P. Lond.
PHYSICIAN TO GUY'S HOSPITAL

There are probably few conditions which bring together the general practitioner and consultant more often than does pyrexia of unknown origin. It holds, also, the major responsibility for shattered reputations and disgruntled relatives. Can any lay person be expected to believe that diagnosis may be quite impossible for several days of fever? The first days of typhoid, paratyphoid, influenza, and even measles may defeat the ablest clinician, who should be wise enough to admit it, rather than to commit himself to a diagnosis just to keep the family quiet. The term "influenza" is the commonest diagnosis of convenience, but it turns upon its creator if followed by the appearance of a rash or signs of a lobar pneumonia.

However, quite apart from the acute fevers whose nature is soon revealed, there exists a host of complaints which may manifest itself for days or weeks only through pyrexia. Now although I suppose every one of us has been baffled more often perhaps than we care to admit in the search for the cause of a pyrexia, it is chastening to remember that the majority of failures are usually due to lack of thoroughness in some routine investigation which does not require extraordinary skill. Of these investigations I put history-taking first of all. When we are considering feverish illnesses with scanty signs our only hope lies in obtaining diagnostic information from the patient. Obvious as this may sound, it can never be too greatly emphasised. As an example, let me quote the case of a doctor whom I saw recently on account of persistent pyrexia.

His history was that on July 21st he had a rigor, vomiting, and a rise of temperature to 102° F. from normal in half an hour. The next day he had frequent rigors, but the vomiting stopped when the bowels had been opened *with an enema. On the 24th he felt* well, the temperature was normal and he started work again, and even played tennis. The only persistent trouble was constipation. This he treated with castor oil on the 26th. The following day the temperature rose, and on the 29th he had to go to bed again with a temperature of 104°. Since that date until August 2nd, when I saw him, his temperature had fluctuated from 98·4 to 100°. There was general slight abdominal discomfort, no nausea, and a good appetite.

Examination.—Pulse, 72; temperatur[illegible] tongue slightly furred. No other physical signs [illegible] at an opaque left antrum which had been infec

bronchial exit of the cavity. Recovery followed the induction of a pneumothorax.

Tuberculous glands in the mesentery are, on the other hand, often overlooked for the very good reason that they may give no definite signs. Here again history is all important. Attacks of shooting right-sided pain, intermittent malaise and loss of appetite, slight loss of weight and particularly loss of vigour are all suggestive. In an attack, localised tenderness is always present and the stools may be pale. In patients over 10 years of age an X ray quite commonly reveals areas of calcification in the right iliac fossa.

Bacillus coli infection of the urinary tract and of the gall-bladder causes a great amount of chronic ill-health and irregular fever. The urinary infection is seldom overlooked except in infants in whom it may cause high fever and vomiting. On the other hand, chronic cholecystitis is probably one of the commonest causes of low grade recurrent pyrexia. It is usually associated with flatulent dyspepsia, but tenderness is very localised, and only to be elicited if the patient breathes deeply against the firm pressure of the palpating finger. A normal cholecystogram in the face of suggestive symptoms, and this sign, should not be allowed to influence the diagnosis.

The only other relatively common cause of obscure fever is *erythema nodosum.* It must be admitted that the obscurity is usually referable to the fact that the legs have not been exposed. Failure to look at a patient's legs is commoner even that failure to look for enlarged glands or disease of the breasts.

Rarer disorders.—It has been my purpose to discuss chiefly the common maladies which produce cryptic fever, so I shall not do more than mention in passing the necessity of considering phlebitis, which may be painless and thus overlooked. Hodgkin's disease (often undiagnosable for weeks), lymphatic leukæmia, malaria, dysentery and tropical abscess, syphilis, rat-bite fever, and allied diseases. Glandular fever has always the adenitis to point the way, and sinus infection, though very common, seldom, in my experience, causes persistent pyrexia.

SUMMARY

(1) Most cases of obscure pyrexia prove to be quite common diseases.

(2) History, examination, and leucocyte count will usually indicate the diagnosis.

(3) Glands, bones, muscles, pelvic organs, and legs must not be overlooked.

(4) Certain drugs such as alkalis in *B. coli* pyelitis, salicylates in rheumatic fever, quinine in malaria, emetine in amœbic abscess, and N.A.B. in protozoal infections may, if all else fails, be the determining agents in establishing the diagnosis.

Although once in several years practitioner and consultant may meet a case of fever which is complex and strange, this is rare. A frank confession of diagnostic sins must include the admission that most failures have been due to careless listening, examining, or thinking rather than to any peculiar pathological rarity.

ROYAL LONDON OPHTHALMIC HOSPITAL.—The King George V. extension of this hospital has been opened by the Duke of York, who was accompanied by the Duchess. The Duke said that the extension of Moorfields was a wonderful tribute to the voluntary hospital system. So far £108,000 had been raised towards the required £113,000, and he hoped that before the end of the Jubilee period the total would be obtained.

EPIDEMIC PEMPHIGUS OF THE NEWLY BORN

(IMPETIGO CONTAGIOSA ET BULLOSA NEONATORUM)

BY W. H. POOLE, M.B. Camb.

AND

C. H. WHITTLE, M.D. Camb., M.R.C.P. Lond.
PHYSICIAN TO ADDENBROOKE'S HOSPITAL, CAMBRIDGE

PEMPHIGUS of the newly born is a highly contagious skin disease which affects infants in the first few days of life. It may occur either in endemic or epidemic form; the latter variety has been rare until comparatively recently, but is now beginning to constitute a serious hospital problem. It is in America that this problem is most acute, widespread epidemics being reported with increasing frequency since about 1917. There is, however, evidence to show that the disease is becoming more prevalent in this country also, and in 1927 the Central Midwives Board issued a pamphlet[1] on the subject, describing, with the aid of a coloured plate, the rash of the disease, and giving suggestions for its prevention and control. An epidemic outbreak occurred in Cambridge during the summer months of 1931, and though adequate details were obtainable in only 9 cases it seems worthy of record if only because of the light which it seems to throw on the ætiology. Before discussing it we propose to review briefly the accounts of pemphigus neonatorum available elsewhere.

HISTORICAL

The earliest description of pemphigus of the newly born was by Ochene[2] in 1773, but it was not until 1864 that Tilbury Fox[3] first drew attention to the contagious nature of the disease, though epidemics had been described by Rigby[4] in England in 1834, and by Leseque and Trousseau[5] in France in 1850. Moldenhauer[6] recorded an epidemic in Leipzig in 1874; in 1886 Demme[7] performed the first bacteriological research into the condition; and Zechmeister[8] in 1887 first drew attention to the part played by the midwife as a carrier. From this time onwards reports were published from various parts of the world with increasing frequency; in 1904 the condition was first reported in America by Call,[9] and in 1912 Dohi and Dohi[10] gave an account of an epidemic in Japan.

The incidence has continued to rise, and Reed[11] has observed that about 1917 a disease which had been comparatively rare and sporadic changed in character and began to appear in nurseries and institutions in an increasingly virulent and epidemic form. This increase has continued.

DEFINITION AND NOMENCLATURE

The disease may take various forms, the lesions being essentially vesicular. But sometimes they become crusted, and at other times lead to widespread exfoliation, so that there is a considerable confusion of terminology. There is no doubt that the conditions described as impetigo contagiosa neonatorum, impetigo bullosa neonatorum, pemphigus neonatorum, dermatitis exfoliativa, Ritter's disease, pemphigoid, and pyodermatitis contagiosa neonatorum are in reality only different forms of the same disease. In this paper the term pemphigus neonatorum is used to cover all the varieties.

little, enough to favour one ear, and the eyelids part just a fraction, so that the whisperers shall be observed. Hysterical stupor, feigned meningitis, and what not can be caught out this way, but there are unfortunately some who are much more versed in the art of being sick.

Once satisfied that the patient is a malingerer, it is, I find, better to deal with her alone. Any audience will produce stubborn resistance. I generally say straight out that I am not in the least impressed by the performance, but that if the patient will start recovering within 24 hours, I will not give her away to her relatives, and will let them assume that whatever disease has been suggested is now passing off. This subterfuge is justified, because no patient can face exposure and will most obstinately go on shamming unless protected by the doctor. One must as it were give her a decent method of escape from the position she has assumed, with the alternative of brutal exposure if she fails to coöperate.

MICROBIAL ORIGIN

Microbic diseases provide us with far and away the largest selection of puzzling cases of fever. The instance which I find has occurred most often in my experience is *infective endocarditis*. The subacute bacterial type is notoriously difficult to diagnose, for the onset is very insidious and the signs slight. The most helpful points are the sickly complexion of the patient (it has been described as café-au-lait), shortness of breath, an invariably raised pulse-rate, slight albuminuria, and the finding of red cells in the urine on microscopic examination. There is almost always an old and recognised rheumatic valvular lesion to assist one, but such diagnostic signs as Osler's nodes, enlarged spleen, clubbed fingers, petechial hæmorrhages, and positive blood culture have often to be awaited for many weeks. Even more frequently I have been consulted on account of fever due to the more fulminant, malignant, or ulcerative type of endocarditis. The reasons for the nature of the disease being overlooked are (1) familiarity with and consequent disregard of the existing valve (usually aortic) lesion; (2) the occurrence of pains in the limbs, which are assumed to be those of a fresh attack of acute rheumatism. Most cases, however, arise in middle life, when recurrence of true rheumatism is uncommon. Again the obvious severe illness of the patient, the pallor, loud murmurs, and sweating should direct attention to the skin, spleen, and urine for evidence of embolism and to the fingers for the early changes of clubbing.

Staphylococcal fever comes high in the list, for it may produce a symptomless fever apart from the usual discomfort of a swinging temperature. Here undoubtedly the most helpful points are (1) leucocytosis of about 12,000 with a relative increase of polymorphs, and (2) a slow pulse in relation to the temperature—e.g., temperature 101° F., pulse 76 to 84. The first point excludes the typhoid group, and suggests pyogenic infection. The staphylococcus is the only common organism to produce such a pulse-temperature ratio. A history of a boil a week or two previously is usually forthcoming, but only if inquiry is made. The development of perinephric abscess as a result of a secondary renal cortical abscess is a common sequel, but it may be symptomless for two or three weeks, or it may give rise to pain referred to the right iliac fossa and lead to operation for appendicitis. The earliest sign may be a gradual rising of the diaphragm on the affected side, with restricted lung excursion; but more often a slight fullness of the loin can be detected if the back be observed from above with the patient sitting forwards. Once the condition is suspected, the loin will, of course, be repeatedly examined for tenderness, and it may be observed also that the patient prefers to keep the thigh on the affected side flexed. It is not fully appreciated that in most cases of so-called perinephric abscess the lesion starts in the kidney and, therefore, the *Staphylococcus aureus* is often to be cultivated from the urine. Residual metastatic abscesses may often perpetuate fever even though the main area of sepsis has been drained. For instance, the prostate, bone, or even muscle may harbour such a focus which may be symptomless until palpated.

Even now we have not exhausted the various revelations of an underlying staphylococcal septicæmia. For instance, I have met two cases of repeated hæmoptysis, wasting, and fever, both originally diagnosed as tuberculosis, and yet proving to be due to staphylococcal lung emboli. In the one case the origin of the infection was eventually traced to the tonsils from which a pure growth of *Staph. aureus* was cultivated; in the other an old gunshot wound of the thigh formed the site of original infection. The value of a leucocytic count in both cannot be over-emphasised.

Streptococcal septicæmia is far less commonly a source of diagnostic difficulty because there is an initial acute inflammation at the portal of entry; usually the throat.

Food infections come high in this series. By these I mean not only typhoid and paratyphoid fevers, but also diseases arising from associated organisms of the salmonella group and of abortus fever. Headache, dirty tongue, diarrhœa or constipation, pyrexia of 100° to 103° F., nausea and often vomiting may be the symptoms, but diagnosis is extremely difficult. Once again a leucocyte count is of great value, for a leucopenia, or at least absence of leucocytosis, in association with such symptoms and high temperatures is very suggestive of one of the food poisoning organisms. Early bacteriological examination of the stools and urine is always advisable. After a week it is unlikely to be fruitful, but soon after this agglutination reactions develop and may in fact be the sole means of clinching the diagnosis. I have been impressed by the frequency of the *Bacillus aertrycke* in these cases. It should be borne in mind that recent T.A.B. inoculation does not exclude the possibility of typhoid fever. Only a few months ago I saw a lady with signs very suggestive of typhoid who had received full protective inoculation five weeks prior to her being infected in the East. The agglutination reactions were temporarily dismissed on the assumption that the vaccine was responsible for them. A few days later rose spots and pea-soup stools pointed unhesitatingly to the diagnosis which was confirmed by a rising titre and falling white count.

Pulmonary tuberculosis does not feature very largely in this series because slight fever with loss of weight and appetite rarely fails nowadays to lead to X ray investigation. Nevertheless, one of the most puzzling cases I have met was presented by a young woman who proved to have a small cavity in the right lung with no surrounding infiltration. Her symptoms were attacks of fever (temp. 100° F.) lasting for 8 to 16 hours. The attacks occurred about once a month and were ushered in by shivering. There was slight loss of weight but no cough. The only physical sign was diminution of movement of the right side of the chest. Presumably these remarkable outbreaks were due to temporary plugging of the as to involve almost the whole body, leaving a moist red surface beneath. The first case of the Cambridge epidemic was of this type, and it is curious that in many of the epidemics recorded the initial case presents severe exfoliation, its successors being milder. This was observed by Cole and Ruh,[18] whose first case showed severe exfoliation and proved fatal; by McCandlish,[23] with whom 3 severe and exfoliative cases, ending fatally, were followed by 221 mild cases, with no deaths; and by Swendson and Lee,[25] who reported a series of cases between March, 1929, and October, 1930, of which only the first showed generalised and severe exfoliation.

The second class contains the majority of cases. The size of the lesion, and whether a bulla or a vesicle, varies in different epidemics, and is of little significance, except that with large bullæ coalescence and exfoliation are commoner.

The third class contains the rare cases, with crusted lesions, as already described. Umbilical sepsis has been suggested as a focus of the infection in pemphigus of the newly born. This is contradicted by the fact that in many of the cases there is no evidence of such sepsis, and also by the fact that the early lesions seldom appear in the umbilical region. Cole and Ruh [18] think that umbilical sepsis is far more likely to be secondary to pemphigus, and hold that in fatal cases the commonest cause of death is bacteræmia due to such infection.

SOURCES OF INFECTION

There can be little doubt that in the Cambridge epidemic the source of infection was Nurse A., who came in contact with all the babies except one. Inquiries revealed that no other person had come in contact with all the children before the outbreak. When this probable cause of the spread of infection was discovered the nurse was suspended from duty, and only one baby born subsequently was affected. This child did not live near to any of the other children, and no person could be traced who could have conveyed the infection from them. But Nurse B., who delivered and attended the infant, came from the same nursing-home as Nurse A., and it seems reasonable to suppose that, by contact with a carrier, she herself became a temporary carrier of the disease.

Some days before the birth of the first child, Nurse A. had a small perionychial whitlow. This had almost healed when the child was born, but it cannot be overlooked as a possible source of the infection.

The avenues by which the disease may spread are numerous.

It has long been recognised that the *lying-in nurse* is often the carrier of the infection; thus in 1887 Zechmeister [8] reported 28 cases from one midwife; in 1901 Jukovsky [26] encountered 12 cases delivered by the same nurse, and in 1903 Maguire [17] reported an epidemic of 18 cases, all except one of which came from one lying-in nurse.

The *mother* also may be the source of infection. Labhardt and Wallart [27] reported 16 cases of congenital pemphigus, and Reed [11] added 11 more; in these cases the infection appears to have been intra-uterine. Freeman records a hospital epidemic which is believed to have started from a congenital case. Mellon, Caldwell, and Winans [28] ascribed four outbreaks which occurred in nurseries to the presence of staphylococci in the mothers' milk; but Benians and Jones [24] thought this conclusion unjustifiable. Infected vaginal tears were considered by Cole and Ruh [18] as another source by which the child could become infected from its mother.

Falls [21] came to the conclusion that the infection might have its origin in any of the common pyococcal *skin infections*, such as impetigo or acne, in those who have to do with children. Reed [11] states that at times the physician is a carrier, particularly the general practitioner, who has to attend patients with open sepsis as well as doing obstetric work. In addition, all who come in contact with the cases, or in contact with carriers of the disease, are themselves liable to become carriers. Benians and Jones [24] and Swendson and Lee [25] have shown that *S. aureus* may be carried on the skin of apparently healthy subjects for considerable periods. Barber [29] points out that cocci from an active boil become scattered widely over the skin of the patient, who thus becomes a "pyococcus carrier." By contact with others he conveys the cocci, directly or indirectly, from his skin to theirs.

Finally, the disease may be transmitted by the contents of *hospital and nursery*, especially clothes, which may harbour specific organisms. Thus Schultheiss [19] traced an epidemic to hospital linen handled by a sorter with a suppurating paronychia.

The Cambridge epidemic illustrates spread of the disease by three of these avenues. In 8 cases infection was almost certainly spread by Nurse A., who was a carrier; in the last case it was apparently contracted from Nurse B., who became a carrier by contact; while one child (as already mentioned) was reinfected by his own clothes after being discharged cured.

ONSET

The bullæ characteristic of the disease usually appear within the first few weeks of life, and are the first sign. Collins and Campbell [30] found that in 6 out of 50 cases the onset was in the first four days of life; in 35 it was between the fourth and the eleventh days; while in the remaining 9 it was between the eleventh and twenty-first. Labhardt and Wallart [27] have recorded 16 cases in which the lesions were present at birth, and Reed [11] 11 others. Onset after the third week is rare, and the course is usually atypical.

In the Cambridge outbreak the day of onset was ascertainable in 8 cases, as follows: third day, 1; fourth, 3; sixth, 1; eighth, 3. Hofmann [31] maintained that an early onset was an indication of greater severity, but this does not agree with our experience.

The first lesion may be in almost any part of the body, though certain sites are commoner than others. In Collins and Campbell's [30] series of 50, it was on the groin in 17 cases, the lower abdomen in 10, the legs is 10, and the face in 3; in the Cambridge outbreak it was on the face in 2 cases, and in the other 7 was on the lower abdomen, leg, groin, axilla, neck, and fingers. The sites of election for the first lesion are evidently points of trauma: the napkin area and its surroundings because they are constantly irritated, and the face because it is readily accessible to scratching.

Three of our cases showed a latent period between exposure to infection and the appearance of lesions; for Nurse A., the carrier, who delivered the children, did not attend them afterwards, yet the lesions did not appear till the third, fourth, and sixth days. The latent period presumably depends on opportunities for inoculation by trauma, and Swendson and Lee [25] suggest that much bathing, rubbing with towels, and warmth and moisture from overclothing may encourage an outbreak to develop.

COURSE AND SYMPTOMS

Most of the Cambridge cases were mild and self-limited. In the 7 which recovered the lesions lasted over periods ranging from 18 to 27 days, the average being 22. Swendson and Lee [25] record a similar observation. In these mild cases the lesions appear

THE CAMBRIDGE EPIDEMIC

During July and August, 1931, a total of 9 cases came under our observation. The period during which new cases appeared was four weeks, and the epidemic lasted seven weeks. No cases were reported in the district after these.

There were two deaths. The first baby was very ill, ran a high temperature, showed complete desquamation of the horny layer over the whole body, and died a few hours after admission to hospital a week after the onset. The second death occurred in a seven weeks' premature child, who in the first three weeks was hardly ill in spite of extensive lesions. This child weighed only four pounds and was weakly from the first.

The other 7 cases were mild in degree, practically afebrile, with lesions varying from a pin's-head to a florin in size. No complications ensued except that in the fourth case an onychial infection developed on one finger and the nail was shed, and in the fifth case there was a recurrence of the disease after the child had been discharged from hospital clear of infection. The fresh infection was due to renewed contact with the clothes worn before admission.

BACTERIOLOGY

The bacteriology of pemphigus neonatorum has been the subject of much controversy.

The first observation was made in 1886 by Demme,[7] who isolated and cultivated a "non-chromogenic diplococcus" from the lesions of the disease. In 1891 Almquist[12] isolated, from the fluid in the lesions, an organism which was culturally and morphologically indistinguishable from *Staphylococcus pyogenes aureus.* He inoculated this organism into himself and produced a vesicular eruption, whereas the ordinary *S. aureus* produced a lesion of follicular type. Considering this an important point of distinction, he gave to the organism which he had isolated the name of "micrococcus pemphigi neonatorum."

In 1900 confusion was caused by Sabouraud[13] who obtained from the lesions of the crusted form of the disease a mixed growth of staphylococci and streptococci, and came to the conclusion that the latter were the causative agent, the staphylococcal infection being superadded. No further evidence has been produced in favour of this view except by Whitfield[14] in 1903, who described a single case in which he considered the infection to be of streptococcal origin.

Matzenauer[15] in 1900 isolated *Staphylococcus aureus* in pure culture, and concluded that the variety in the form of lesion produced by the organism was due to variations in virulence—an opinion since supported by much important evidence. In 1900 Bloch[16] made observations on 8 fatal cases, and found that although the children had died from streptococcal septicæmia staphylococci were present in the skin lesions. In 1904 Call[9] found staphylococci in the lesions of all the cases examined in an epidemic in an institution, and other observers who have confirmed these findings are Maguire,[17] Cole and Ruh,[18] Schultheiss,[19] Belding,[20] Falls,[21] and many others. Some investigators, notably Clegg and Wherry[22] in 1906, and Falls[21] in 1917, found diplococci and short chains in the lesions with some consistency; McCandlish[23] in 1925 considered these cases, as well as some of his own where diplococci had also been found, and came to the conclusion that they were in reality staphylococci, since on subculture the typical arrangement was found.

Benians and Jones[24] in 1929 made extensive investigations into the bacteriology of the disease. The *Staphylococcus aureus* isolated from all their cases showed no recognisable biochemical or cultural differences from the common *S. aureus* which is the cause of boils and follicular pustules. They also note that a streptococcus was recovered in only one of their cases—an isolated one, not related to an epidemic and in an older infant. They studied the possibility of a filtrable virus being the cause of pemphigus neonatorum, but their results were entirely negative.

Bacteriological investigations were made in 8 out of the 9 Cambridge cases, the only exception being the first case, in which the patient died shortly after admission. An intact bulla was punctured with a fine glass pipette, and the fluid was aspirated; this fluid was then inoculated on to the culture media, which were broth and a special nutrient agar. Bullæ of various sizes were chosen, and in every case the predominating organism was *Staphylococcus aureus* in typical form. In 7 out of the 10 cultures which were made this organism was found in pure culture; in the remaining 3 it was contaminated with a small proportion of *S. albus.* In 2 cases there were a few colonies of *S. albus* amid a large and almost confluent growth of *S. aureus,* and in the other case there were 3 colonies of *S. albus* amongst 37 colonies of *S. aureus.* Particular care was taken by one of us (C. H. W.) in the making of cultures, not only in selecting the earliest and youngest blisters, but also in spacing the inoculum on the medium so that the colonies resulting were not crowded. Special media were used which were designed for cultivating pneumococci and streptococci, and it is extremely unlikely that such organisms if present would have failed to appear in the cultures. Yet in no case were streptococci grown nor were any organisms seen in film other than staphylococci.

In this epidemic therefore the causative organism appears to be the *Staphylococcus pyogenes aureus.* Hæmolytic and serological tests were not performed.

PATHOLOGY

The lesion of pemphigus of the newly born is essentially one which affects the superficial layers of the skin. McCandlish[23] divides the lesions into three types:—

(1) Vesicles which coalesce and then rupture, leaving large areas of exfoliation; this form he regards as identical with the dermatitis exfoliativa of Ritter von Rittershein.

(2) Large discrete bullæ: he considers this form to be relatively rare.

(3) Small vesicles; these may coalesce, but do not lead to extensive exfoliation.

Most of the cases have lesions which fall into one of these classes, though sometimes two or more of the types may be in evidence, or the lesion may change from one to another. Moreover, the types merge into one another (especially 2 and 3) and such classification is purely arbitrary.

A lesion has also been described in which crusts are present. These cases are reported from Japan by Dohi and Dohi[10]; some of the bullæ became covered with thin crusts, the infection otherwise being identical with the forms usually described. A similar lesion was observed in one of the Cambridge cases, in which a bullous eruption upon the abdomen and buttocks existed simultaneously with a crusted lesion upon the neck and scalp. This variation in form made no difference to the course of the disease.

In view of the occurrence of this type of lesion, and the *purely arbitrary differentiation* between McCandlish's second and third types, the following classification seems preferable:—

(1) Exfoliative dermatitis.

(2) Vesicular and bullous lesions, in which extensive coalescence and exfoliation do not occur.

(3) Crusted lesions.

The first class contains the majority of severe and fatal cases. The desquamation may be so severe s to involve almost the whole body, leaving a moist d surface beneath. The first case of the Cambridge pidemic was of this type, and it is curious that in any of the epidemics recorded the initial case resents severe exfoliation, its successors being milder. his was observed by Cole and Ruh,[18] whose first ase showed severe exfoliation and proved fatal; y McCandlish,[23] with whom 3 severe and exfoliative ases, ending fatally, were followed by 221 mild ases, with no deaths; and by Swendson and Lee,[25] ho reported a series of cases between March, 1929, nd October, 1930, of which only the first showed eneralised and severe exfoliation.

The second class contains the majority of cases. he size of the lesion, and whether a bulla or a vesicle, aries in different epidemics, and is of little signi- icance, except that with large bullæ coalescence and xfoliation are commoner.

The third class contains the rare cases, with crusted esions, as already described. Umbilical sepsis has een suggested as a focus of the infection in pemphigus f the newly born. This is contradicted by the fact hat in many of the cases there is no evidence of such epsis, and also by the fact that the early lesions seldom ppear in the umbilical region. Cole and Ruh[18] hink that umbilical sepsis is far more likely to be econdary to pemphigus, and hold that in fatal cases he commonest cause of death is bacteræmia due to uch infection.

SOURCES OF INFECTION

There can be little doubt that in the Cambridge epidemic the source of infection was Nurse A., who came in contact with all the babies except one. Inquiries revealed that no other person had come in contact with all the children before the outbreak. When this probable cause of the spread of infection was discovered the nurse was suspended from duty, and only one baby born subsequently was affected. This child did not live near to any of the other children, and no person could be traced who could have conveyed the infection from them. But Nurse B., who delivered and attended the infant, came from the same nursing-home as Nurse A., and it seems reasonable to suppose that, by contact with a carrier, she herself became a temporary carrier of the disease.

Some days before the birth of the first child, Nurse A. had a small perionychial whitlow. This had almost healed when the child was born, but it cannot be overlooked as a possible source of the infection.

The avenues by which the disease may spread are numerous.

It has long been recognised that the *lying-in nurse* is often the carrier of the infection; thus in 1887 Zechmeister[8] reported 28 cases from one midwife; in 1901 Jukovsky[26] encountered 12 cases delivered by the same nurse, and in 1903 Maguire[17] reported an epidemic of 18 cases, all except one of which came from one lying-in nurse.

The *mother* also may be the source of infection. Labhardt and Wallart[27] reported 16 cases of congenital pemphigus, and Reed[11] added 11 more; in these cases the infection appears to have been intra-uterine. Freeman records a hospital epidemic which is believed to have started from a congenital case. Mellon, Caldwell, and Winans[28] ascribed four outbreaks which occurred in nurseries to the presence of staphylococci in the mothers' milk; but Benians and Jones[24] thought this conclusion unjustifiable. Infected vaginal tears were considered by Cole and Ruh[18] as another source by which the child could become infected from its mother.

Falls[21] came to the conclusion that the infection might have its origin in any of the common pyococcal *skin infections*, such as impetigo or acne, in those who have to do with children. Reed[11] states that at times the physician is a carrier, particularly the general practitioner, who has to attend patients with open sepsis as well as doing obstetric work. In addition, all who come in contact with the cases, or in contact with carriers of the disease, are themselves liable to become carriers. Benians and Jones[24] and Swendson and Lee[25] have shown that *S. aureus* may be carried on the skin of apparently healthy subjects for considerable periods. Barber[29] points out that cocci from an active boil become scattered widely over the skin of the patient, who thus becomes a "pyococcus carrier." By contact with others he conveys the cocci, directly or indirectly, from his skin to theirs.

Finally, the disease may be transmitted by the contents of *hospital and nursery*, especially clothes, which may harbour specific organisms. Thus Schultheiss[19] traced an epidemic to hospital linen handled by a sorter with a suppurating paronychia.

The Cambridge epidemic illustrates spread of the disease by three of these avenues. In 8 cases infection was almost certainly spread by Nurse A., who was a carrier; in the last case it was apparently contracted from Nurse B., who became a carrier by contact; while one child (as already mentioned) was reinfected by his own clothes after being discharged cured.

ONSET

The bullæ characteristic of the disease usually appear within the first few weeks of life, and are the first sign. Collins and Campbell[30] found that in 6 out of 50 cases the onset was in the first four days of life; in 35 it was between the fourth and the eleventh days; while in the remaining 9 it was between the eleventh and twenty-first. Labhardt and Wallart[27] have recorded 16 cases in which the lesions were present at birth, and Reed[11] 11 others. Onset after the third week is rare, and the course is usually atypical.

In the Cambridge outbreak the day of onset was ascertainable in 8 cases, as follows: third day, 1; fourth, 3; sixth, 1; eighth, 3. Hofmann[31] maintained that an early onset was an indication of greater severity, but this does not agree with our experience.

The first lesion may be in almost any part of the body, though certain sites are commoner than others. In Collins and Campbell's[30] series of 50, it was on the groin in 17 cases, the lower abdomen in 10, the legs is 10, and the face in 3; in the Cambridge outbreak it was on the face in 2 cases, and in the other 7 was on the lower abdomen, leg, groin, axilla, neck, and fingers. The sites of election for the first lesion are evidently points of trauma: the napkin area and its surroundings because they are constantly irritated, and the face because it is readily accessible to scratching.

Three of our cases showed a latent period between exposure to infection and the appearance of lesions; for Nurse A., the carrier, who delivered the children, did not attend them afterwards, yet the lesions did not appear till the third, fourth, and sixth days. The latent period presumably depends on opportunities for inoculation by trauma, and Swendson and Lee[25] suggest that much bathing, rubbing with towels, and warmth and moisture from overclothing may encourage an outbreak to develop.

COURSE AND SYMPTOMS

Most of the Cambridge cases were mild and self-limited. In the 7 which recovered the lesions lasted over periods ranging from 18 to 27 days, the average being 22. Swendson and Lee[25] record a similar observation. In these mild cases the lesions appear in one place, and for the next fourteen days the tendency is towards spread. This is by contiguity, in the form of recurrent crops of bullæ on an increasing area around the original site, and also indirectly, as shown by the occurrence of bullæ on other parts of the body. In all but 2 cases this spread to other sites was noted. It was observed that the secondary spread was almost always to sites which the child could readily reach with the fingers, the commonest being the face and groins. Accordingly the child's arms were splinted after admission to hospital, and the result was that no lesions developed on new sites.

Twelve to twenty days after the onset the appearance of fresh crops of bullæ suddenly ceases, and rapid healing takes place. Within six or seven days of this time healing is complete.

The disease therefore may be said to have three phases: (1) a period of latency, apparently of 2–3 days; (2) a period of spread, averaging about 14 days; and (3) a period of healing, usually about a week.

A striking feature of these cases was the local character of the disease and the mildness of constitutional symptoms. The babies took their food and put on weight during the whole course of the illness; they slept normally, and appeared to be perfectly well. Pyrexia was almost absent; in only one case did the temperature rise more than 2° above the normal, and then only for a short time. A striking testimony to the mildness of the infection was furnished by the case of the premature infant already referred to. It seemed so feeble that its survival seemed impossible; yet, although it ultimately succumbed with respiratory complications, it remained alive and appeared to thrive for 24 days after the onset of the disease, abundant crops of bullæ appearing during the whole period.

In the more severe type the onset is similar, but the bullæ are larger and spread with greater rapidity. They coalesce with extensive exfoliation, and the large raw weeping areas which are left may cover the whole body. There is considerable constitutional disturbance, the child being gravely ill with high fever. Death is a common sequel, the cause being a staphylococcal septicæmia, which Cole and Ruh [18] and others attribute to the infection involving the umbilicus. The duration of this type is often short; thus, Swendson and Lee's [25] case died on the fourth day, and the reports of Cole and Ruh [18] McCandlish,[23] Bloch,[16] Almquist,[12] and others show that such cases seldom survive beyond the twelfth day.

The first case of the Cambridge epidemic was of this severe type. The child had been ill a week before admission to hospital, the temperature was 104·8°, and the desquamation involved almost the whole body, large ragged pieces of epidermis hanging on by shreds. Death occurred within an hour of admission; unfortunately, permission for a post-mortem examination was refused.

DIFFERENTIAL DIAGNOSIS

The diagnosis is not as a rule difficult, but confusion may be caused by the following conditions:—

(1) In *pemphigoid syphilide* the eruption is symmetrical, and chiefly on the buttocks, palms, and soles. Other symptoms and signs of congenital syphilis are almost always present, and the Wassermann reaction is positive.

(2) *Impetigo contagiosa* is characterised by the formation of thick crusts, especially on the face and scalp.

(3) *Pemphigoid eruptions due to drugs* are uncommon, but may be caused by bromides, bismuth, or the heavy metals. A careful history is required.

(4) In *bullous varicella of the newly born* the diagnosis is often difficult, but there may be a history of exposure to infection. The eruption is usually generalised and accompanied by considerable constitutional symptoms.

(5) *Dermatitis herpetiformis* (Duhring's disease) is rarely seen in the first weeks of life, and is characterised by severe itching. The condition is a toxic one, and the contents of the bullæ are always sterile.

(6) *Epidermolysis bullosa* is an hereditary condition in which the bullæ appear after slight trauma, chiefly on exposed extensor surfaces.

(7) *Hydroa vacciniforme* is an actinic eruption, almost confined to the male sex, and attacks only the parts of the body exposed to light. It is very rare in young infants.

In all cases of doubt the diagnosis can be confirmed by the examination of fluid from one of the bullæ or vesicles. The discovery of abundant *Staphylococcus aureus* in this fluid is pathognomonic.

PROGNOSIS

In prognosis one must distinguish between the severe exfoliative cases, which run a short course and almost always end fatally, and the mild ones in which the child is not ill, the course is longer, and recovery takes place. Most of the recorded epidemics have begun with one or more cases of the first type, after which the remaining cases have run the more usual mild course. In large epidemics, therefore, the mortality-rate is relatively low; thus Almquist [12] records 134 cases with 4 deaths; Falls [21] 2 deaths in 47 cases, and McCandlish [23] only 3 deaths in 221 cases. In the smaller outbreaks in which the severe initial cases occur in the same way but the spread of infection is rapidly controlled, the percentage mortality naturally appears much higher. Maguire [17] had 8 deaths in 18 cases, and Knowles [32] 10 in 30. Of the 2 fatal cases in our own series of 9 one was due to the initial severe exfoliative lesion, but the other was in a premature child, and the pemphigus appeared to be only a small factor in its causation.

TREATMENT

The treatment falls into three phases: (1) prevention; (2) control of epidemic; (3) treatment of cases. Prevention depends on infants not being handled by anyone who is suffering from, or in contact with, an infective condition; and on scrupulous obstetric cleanliness and a rigorous nursing technique. The prevention and control of outbreaks has been especially studied in America (Olmsted,[33] Dickey,[34] Rood Taylor,[35] and Rulison.[36])

In treatment of the actual cases the most satisfactory results are obtained by frequent cleansing with a mild antiseptic, followed by a dry dressing. Gregorson [37] claims to have obtained good results from repeated exposure to ultra-violet light, whilst Cole and Ruh [18] think that the use of an autogenous vaccine is beneficial. But it seems likely that simpler measures are equally good.

In the Cambridge epidemic the cases were all isolated in a "septic ward"; special nurses who attended no other cases were responsible for the dressings, which were renewed every four hours by day, and once during the night; if the dressings became soiled by excreta they were changed at once. Whenever the skin was dressed, all unbroken blisters were pricked with a sterile needle. In all cases the babies' arms were splinted to prevent the spread of infection by scratching. The five methods of treatment employed were as follows:—

(1) The blisters were pricked with a sterile needle; the affected area was then washed four-hourly with a 1/6000 solution of perchloride of mercury in normal saline at 100° F., and sprinkled with zinc oxide powder,

and covered with a dry dressing. This method was used only for one case.

(2) The blisters were pricked as above, washed four-hourly with warm olive oil, and dressed with calamine liniment containing ichthyol grs. 15 to the ounce. Three cases were treated by this method, and all did well.

(3) The lesions were pricked and washed with olive oil as above, and then dressed with calamine liniment containing 2 per cent. of "white precipitate." This method was used for four cases, and in all it appeared beneficial.

(4) The child was bathed six-hourly in a bath containing ¼ lb. boric acid to 10 gallons of water, and the lesions then dressed with boric acid ointment. The one case in which this treatment was used did well.

(5) A stock *Staphylococcus aureus* vaccine was used in one case, injections of 20 millions, 50 millions, and 100 millions being given at intervals of two days. Practically no reaction followed the administration of the vaccine, and the treatment did not appear to have any effect on the course of the disease.

The methods (2), (3), and (4) all gave good results and there seemed to be little to choose between them.

CONCLUSIONS

Epidemic pemphigus, or bullous impetigo of the newly born, is a highly contagious disease, increasing in incidence. It is due to infection by the *Staphylococcus aureus,* and is usually conveyed by the personnel or impedimenta of the lying-in room. The organism is carried on the skin of the carrier, and is conveyed by direct contact to the skin of the infant. Clinically there are two forms: the severe exfoliative, which is rapidly fatal, and the mild, which tends to run a self-limited course with remarkably little constitutional disturbance. At the onset of an outbreak there are usually one or more severe cases, and the subsequent cases are commonly much milder. The essentials of the treatment are mild antiseptic cleansing and dressing.

THE EFFECT OF HIGH PROTEIN DIET ON ARTERIAL PRESSURE IN CASES OF HYPERTONY

BY I. HARRIS, M.D. Königsberg, L.R.C.P. Edin.
HON. PHYSICIAN TO THE LIVERPOOL HEART HOSPITAL

C. N. ALDRED, M.D. Manch.
RESEARCH FELLOW AT THE HOSPITAL; AND

A. G. HAWTHORNE ENGLISH, M.R.C.S. Eng.
CLINICAL ASSISTANT AT THE HOSPITAL

IN this investigation an attempt has been made to re-examine the part protein plays in cases of hypertony, as regards both ætiology and treatment. Our object has been to discover the immediate effect which a high and low protein diet may exercise on high blood pressure. It is conceivable that a high protein diet by increasing the serum protein raises the colloidal osmotic pressure and in this way sets a compensatory mechanism in action which increases the hydrostatic pressure. On the other hand, it is possible that the end-products of protein, such as urea, may be factors in causing hypertension. We did not find serum protein consistently increased, and we therefore will deal in this paper with the end-products of protein only.

The plan of investigation was as follows: The patients were confined to bed throughout, and were weighed daily, fluid intake and urinary excretion being charted as a routine. All had a preliminary period, usually a week, in bed without treatment before the investigations commenced. The following régime was then followed:—

Two weeks on low protein diet. This was a diet of 30 g. of protein daily.

Two weeks on high protein diet. (1 lb. lean beef daily, 100 g. protein.)

Two weeks of low protein diet repeated.

The patients were bled, from the veins of the antecubital fossa (1) on the morning on which the observations started; (2) on the 8th day of the diet; (3) on the 15th day. Serum protein was estimated as well as the albumin and globulin ratio. Refractometric readings were taken, and the non-protein nitrogen and urea of the blood were determined; also in some cases osmotic pressure and blood chlorides. A kidney efficiency test was performed in all cases.

The figures set out in the accompanying Table suggest at first sight that high blood pressure is unaffected by alteration of the protein content of the diet from high to low or vice versa. If, however, the non-protein nitrogen (N.P.N.) figures are considered in conjunction with arterial pressure readings, then a relation becomes manifest between high protein diet, high blood pressure, and N.P.N. In cases where a high protein diet does not raise the blood pressure there is an increase of N.P.N.; whereas in cases where it raises the blood pressure conspicu-

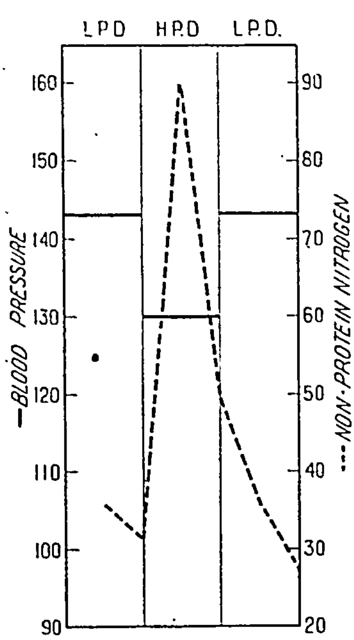

FIG. 1. (Case 4).—Average systolic blood pressure and non-protein nitrogen on low and high protein diets. On a high protein diet the N.P.N. rose while the systolic blood pressure fell.

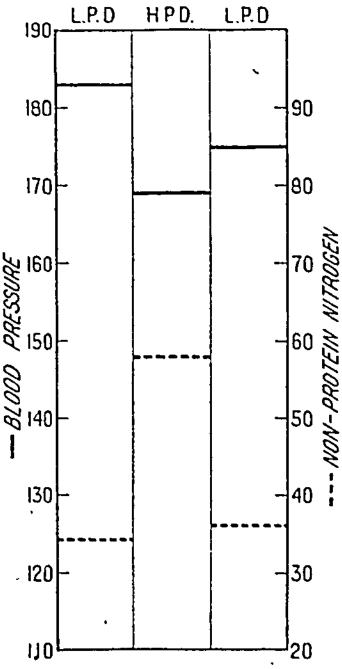

FIG. 2.—Composite curve. Cases 1, 2, and 4. Here, too, the effect of the high protein diet is to lower the systolic blood pressure and raise the N.P.N.

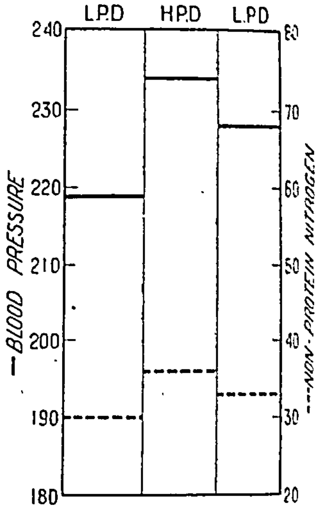

FIG. 3.—Composite curve of three cases (Nos. 3, 5, and 12) in which the effect of the high protein diet was to raise the systolic blood pressure. In these cases the N.P.N. has not markedly increased.

ously the value of N.P.N. does not increase and may even become lower. Comparison of the N.P.N. and urea figures shows clearly that where the pressure falls the N.P.N. rises (Figs. 1–3).

Obviously the rise of pressure taking place after increased protein intake is an adaptation for the purpose of assisting the kidney to remove protein end-products. In cases where the blood pressure does not rise, the end-products accumulate in the blood stream. We have reason to believe that the end-products of protein are not the only substances which raise pressure in this way. Other constituents of the blood in abnormal quantities, such as salt, bring the same adaptive mechanism into action. The cases here summarised belong to different types of hypertony, but those which are usually labelled essential hypertony react in this respect in the same way as those high blood-pressure cases which are associated with frank renal disease. We find that the administration of 30 g. of urea increases the blood pressure; on the other hand the lowering of pressure by sulphur injections results in an increase of the N.P.N.

CONCLUSION

When a high protein diet is given the arterial pressure stands in inverse ratio to the non-protein-nitrogen serum content. Where there is an adequate rise of arterial pressure, the N.P.N. content is not increased, and vice versa.

CLINICAL AND LABORATORY NOTES

GASTRIC CARCINOMA WITH NORMAL ERYTHROCYTE SEDIMENTATION REACTION

BY L. J. WITTS, M.D. Manch., F.R.C.P. Lond.

DIRECTOR OF THE MEDICAL UNIT, ST. BARTHOLOMEW'S HOSPITAL; PROFESSOR OF MEDICINE IN THE UNIVERSITY OF LONDON

THE sedimentation reaction depends on the observation that when a sample of citrated blood is taken from a patient with pregnancy, infection, or malignant disease, the red cells fall out of suspension more rapidly than in health, and a clear layer of plasma, whose depth varies with the intensity of the disease, appears within a short time at the top of the tube. The test is increasing in popularity in this country for the detection of obscure organic disease, but the following example shows that it may be negative with advanced malignant disease.

A man of 32 was admitted to this hospital with 2½ years' history of anorexia, nausea, and vomiting. For a year he had had pain between the shoulders and along the right costal margin. He had lost 3 st. in weight. He came to us soon after a stay of two months in another London teaching hospital, where X ray examination of the alimentary system had shown no organic disease, and a diagnosis of nervous dyspepsia had been made. The man looked ill, though physical examination was negative and he was not anæmic. A fractional test-meal showed achlorhydria of the benign type with excess of mucus but no bleeding; unfortunately he vomited when the tube was passed, and the resting contents of the stomach were not examined. A little free hydrochloric acid was secreted after the injection of histamine. The stools constantly contained occult blood.

The erythrocyte sedimentation reaction by the standard Westergren method was normal, 3 mm. in one hour. Thinking that the patient's symptoms might be due to gastritis, I asked Mr. H. W. Rodgers to examine him with the gastroscope, which revealed an ulcer with everted margin near the incisura angularis. On X ray examination there was a persistent filling defect of the pyloric antrum. The sedimentation reaction was repeated by the same technique but by another observer, and again the result was normal, 7 mm. in one hour. Sir Charles Gordon-Watson decided in favour of operation and performed a subtotal gastrectomy for a saddle-back growth of the stomach which extended from the pyloric antrum 3½ inches along the lesser curvature. There were hard enlarged glands along the greater and lesser curvatures, but no other metastases were seen. Sections showed that the growth was a spheroidal-celled carcinoma, and that the neighbouring glands contained secondary deposits.

PRIMARY STAPHYLOCOCCAL PERITONITIS IN A CHILD

BY R. SAUNDERS MELVILLE, M.B. St. And., F.R.C.S. Edin.

CONSULTING SURGEON TO ARBROATH INFIRMARY, DUNDEE

THE following case of primary staphylococcal peritonitis occurred in the practice of Dr. F. M. Davidson, of Arbroath, and the patient was admitted to the Arbroath Infirmary by Dr. J. W. Tocher, his partner, with whom I saw her in consultation.

A. B., a girl aged 6, complained of feeling unwell on the morning of Sept. 1st, 1934, and vomited in the evening. Next day she had pain and tenderness over the abdomen; diarrhœa developed and she vomited again. During the two following days she became worse. She was given Epsom salts, vomited immediately thereafter, and again had diarrhœa. She was seen by her doctor and admitted to the infirmary on the afternoon of Sept. 5th.

When seen in consultation the child looked very ill. The face was cyanosed, the eyes sunken, and she was semi-stuporose. The pulse-rate was 126; the temperature 101° F. The tongue was coated and the breath foul. Breathing was restrained, and there was limitation of abdominal movement. The whole abdomen was rigid on palpation; tenderness was generalised but greatest to the right of and below the umbilicus. Pneumococcal peritonitis was considered, but in view of the clinical findings a diagnosis of perforated appendix was made and the abdomen was opened by a gridiron incision. As it was opened a very little straw-coloured fluid escaped. The appendix was injected, but was obviously not the primary cause of the condition. Investigation revealed a generalised peritonitis, the terminal ileum being injected and covered with lymph. There was no matting of the coils, no gross distension, and very little fluid in the pelvis. A smear was taken from the pelvis and the appendix was then removed, a rubber dam drain being inserted. The child's condition after operation was precarious, and subcutaneous saline was administered continuously for the first 24 hours. After 48 hours the condition began to improve. Little had escaped by the drain, and this was removed after 48 hours. On the 15th, ten days after operation, the pulse and temperature were normal. The child was discharged well sixteen days after operation.

The smear and appendix were submitted to Prof. W. J. Tulloch, of the bacteriological department, University of St. Andrews, and he reported that the swab from the peritoneum gave a pure culture of *Staphylococcus aureus*—a finding borne out by microscopical examination. Staphylococci were also recovered from the appendix, together with *Bacillus coli*.

The staphylococcus is referred to in most surgical text-books as an uncommon cause of primary peritonitis, and few cases of this kind appear to be on record.

Fishbein [1] found in 125 cases of peritonitis, 32 primary. Among these staphylococci were found 12 times, 3 times in pure culture and 9 times mixed. Neff [2] states that "the infective organism is commonly the pneumococcus or streptococcus, occasionally a staphylococcus or colon bacillus." De Sanctus and Nichols [3] in 21 cases of primary peritonitis found in 1 *Streptococcus hæmolyticus* and *Staphylococcus aureus* together. Obadalek [4] reports 1 fatal case (staphylococcal) in 50 genuine cases of peritonitis in children. Lazarus [5] investigating 42 consecutive cases of acute peritonitis in children found pneumococci and streptococci most often. Other organisms were *B. coli* (2 cases), staphylococcus (1 case), and unidentified organisms (4 cases), either alone or with streptococci.

The probability is, however, that many cases are not reported, and that many others are ascribed to peritonitis of appendicular origin. It seems reasonable to suppose that the source of infection is the alimentary tract, and that the condition arises after a "stomach upset" in which the digestive juices no longer exercise their normal protective functions. A fatal enteritis due to staphylococcal infection can arise under such circumstances. In the case under review stomatitis and gingivitis were reported on the 15th, but in view of the patient's post-operative condition too much stress cannot be laid upon this as evidence of a definite infection from above.

I am indebted to Dr. M. Schwartz, [illegible] medical officer at Arbroath Infirmary, for the notes on this case.

A CASE OF CONCEALED ACCIDENTAL HÆMORRHAGE

By A. W. Vaisey, M.B. Camb.

LATE HOUSE PHYSICIAN, ST. THOMAS'S HOSPITAL MEDICAL UNIT

Concealed accidental hæmorrhage in its classical form is a rarity, being, like lithopædion and locked twins, very much of a text-book condition. Although the following case comes strictly into the category of a mixed hæmorrhage, the bleeding was almost entirely internal, and the case presented several interesting features.

A woman of 30, with a history of two previous confinements, both normal, was admitted to hospital complaining of slight brownish discharge from the vagina for the past fourteen days. She believed herself to be about six months' pregnant, and stated that for the past few days she had been growing rapidly paler, in spite of only a slight external staining per vaginam. There was no abdominal pain or backache, no increase in the respiratory excursions, and no thirst; in fact, there was no discomfort whatever. The pulse-rate was 76, and the temperature subnormal. The general physique was good, but great pallor of the skin and mucous membranes confirmed the patient's story. There was a complete lack of striæ gravidarum; abdominal palpation revealed a uterus that corresponded in size with a full-term pregnancy, but was everywhere unusually tense although not in the slightest tender. No fœtal parts could be made out; nor could the fœtal heart sounds be heard. Vaginal examination revealed a high cervix with an os just admitting one finger; the presenting part could not be determined, although it was certainly not head nor placenta.

Although there were no symptoms of concealed hæmorrhage apart from the obvious pallor, no other diagnosis could be entertained, and a conservative attitude was adopted. An initial dose of morphia gr. $\frac{1}{4}$ was given after the examination, the foot of the bed raised on 6 in. blocks, and thereafter pot. brom. and chloral hyd. āā grs. xx. four-hourly was given, with fluids ad lib. There was no change for three days except that the vaginal loss was slightly increased; a small daily enema sufficed for the bowels.

On the fourth day, with dramatic suddenness, a rigor appeared, with profuse sweating, pulse 120, and temperature 102° F. There was still no alteration in the respiratory excursions, and no abdominal pain or tenderness. Opoidine gr. $\frac{1}{3}$ was at once administered, and the second and final vaginal examination revealed no change in the condition of the cervix. Ten hours later the rigor, pulse-rate, and temperature had subsided, when for the first time the patient complained of abdominal pain, and within five minutes she was delivered precipitately of footling, placenta, about 30 oz. of blood clot, and remainder of fœtus, in that order. The fœtus, which was slightly macerated, corresponded to about 32 weeks gestation; the placenta was heavily infarcted. For an hour the patient was considerably shocked, but an injection of 10 units of pituitrin, given immediately, gave an entirely satisfactory uterine contraction and retraction, and there was practically no post-partum oozing. Rectal salines with brandy 2 drachms four-hourly were prescribed, and in 24 hours the patient was remarkably fit.

Unfortunately convalescence was not uneventful, as 48 hours after delivery the temperature rose to 103° F. and the lochia became offensive. Intensive treatment, however, overcame the infection, and then with the aid of massive doses of iron the patient was discharged well six weeks later.

The interest of this case consists in (1) the very large internal hæmorrhage which must have occurred before admission, with practically no symptoms except pallor; (2) the occurrence of a single rigor which had completely abated before the onset of precipitate labour; and (3) a recovery which showed every sign of being complete and rapid if puerperal infection had not intervened.

MEDICAL SOCIETIES

LONDON ASSOCIATION OF THE MEDICAL WOMEN'S FEDERATION

At a meeting of this society on May 28th, with Dr. E. Pickard, the president, in the chair, Dr. D. S. Russell spoke on

Some Aspects of Pituitary Function

After a few introductory remarks on the anatomy of the pituitary body and hypothalamus, she discussed the cytology of the anterior lobe and gave the reasons for the belief that the acidophil (alpha) and basophil (beta) cells were derived by transition types from the non-granular or so-called chromophobe cells. Recent work by Severinghaus on the Golgi apparatus of these cells had pointed strongly in the same direction; the form of the apparatus, as demonstrated by osmic acid methods, was different in the two types of granular cell and corresponding forms of the apparatus were to be found in the chromophobe cells. From this it was to be inferred that each chromophobe cell was predestined as a precursor of one or other of the two types of granular cell. There was no doubt that the so-called pregnancy cell was of the transitional acidophil type and not of the chromophobe series, as some writers had asserted.

Recent work on the isolation and investigation of the various anterior lobe hormones was then briefly reviewed. At the present time the existence of seven or eight different hormones had been widely accepted, and there were indications that one or two more might be added to the list in the near future. Human pathology as yet threw little light on the sites of elaboration of these hormones in the anterior lobe with the outstanding exception of the growth hormone. There was incontrovertible evidence that this is secreted by the acidophil cells. The possibility that the gonadotropic hormone is formed by the basophil cells had been entertained in many quarters but could not be regarded as an established fact. The effects upon the organism of partial and total ablation of the anterior lobe had been clearly demonstrated experimentally and were recognised in human pathology both in the pituitary cachexia of Simmonds's disease, associated with complete or almost complete destruction of the anterior lobe, and in the combined dwarfism and infantilism usually described as of the Lorain type. Dr. Russell described a case of acute pituitary cachexia following upon division of the stalk in a case of suprasellar Rathke's pouch cyst and also one of pituitary dwarfism, associated with a large suprasellar Rathke's pouch cyst.

Excessive pituitary secretion, she said, was exemplified in human pathology by gigantism and acromegaly in which the disturbance was correlated with an

of Manouvrier. This shows clearly that, while mesatiskelety gives an index of 90, let us say, macroskelety may give one of 100 and brachyskelety one of 81 or 82, but it also shows that, whereas the normal index remains practically constant during the years of puberty, the two subnormal states increase their differences. When this is taken into account with the marked changes in the development of the upper and lower parts of the thorax in these states, it seems likely that the facts possess some clinical interest; in any case they offer a clearer conception of the conditions than that presented by the rather indefinite "sthenic" and "asthenic" types of constitution of which one hears occasionally. A chapter on the little-known effects of puberty on the pigments of the eye brings to an end this important book, which will doubtless remain the classic work on the bodily facts of growth.

Occupation and Health

Vol. II. *Encyclopædia of Hygiene, Pathology, and Social Welfare.* International Labour Office. London: 12, Victoria-street. 1934. Pp. 1310. Both Vols.—£4 paper; £4 7*s.* 6*d.* cloth.

THE second volume of this compilation completes a comprehensive work, the first part of which was published in 1931. This volume deals with subjects in alphabetical order from I to Z. The headings relate to diseases, to groups of persons according to occupation, to particular occupations or to special substances causing risk to those brought in contact with them at work. Each subject is dealt with under subheadings, varying according to its nature, but, in most cases, including symptoms, diagnosis, pathology, prophylaxis, statistics, hygiene, legislation, and bibliography. Facts are drawn and instances given from all industrialised countries, so that a mass of information is brought together which cannot readily be found elsewhere. It would be too much to expect that a publication of this kind should distinguish the more from the less significant data it furnishes; discrimination must be left to the reader. Since the encyclopædia has taken several years to compile it is, of course, not completely up to date in its facts, so that it will be of less use to the specialist in occupational diseases than to those whose contact with such diseases is occasional and unofficial. Purchasers would be well advised to obtain the cloth-bound volumes, which are only 7*s.* 6*d.* dearer than the paper-bound. For a book of this size and weight even strong paper covers are unsatisfactory.

Text-Book of Surgery for Dental Students

Fourth edition. By G. PERCIVAL MILLS, M.B., B.S., F.R.C.S., Hon. Surgeon, General Hospital, Birmingham; and HUMPHREY HUMPHREYS, M.B., M.D.S., L.D.S., Hon. Surgeon, Birmingham Dental Hospital. London: Edward Arnold and Co. 1934. Pp. 342. 14*s.*

THIS book is designed to give dental students a general idea of surgery and its principles combined with more detailed knowledge of affections of the mouth and face. It is admittedly a very difficult task to review the whole of surgery in a small compass, and at the same time to avoid inaccuracies. On the whole the authors have been successful, but it is regrettable that more care was not taken in the revision of those parts of surgery which are of direct interest to the dental student. For example, the recommendation made on p. 203 and repeated on p. 241, to remove the premaxilla in the treatment of bad cases of cleft palate, is good neither from a surgical nor dental standpoint. Again, the suggestion made (p. 288) that large dental cysts which invade the antrum of Highmore after operation will become obliterated by new bone formation can scarcely be based upon observation. In other sections of the book there are misstatements, but these being outside the usual purview of the dentist, are perhaps of less importance. The work is excellently printed and illustrated.

Aids to Surgery

Sixth edition. By CECIL A. JOLL, M.S., F.R.C.S., B.Sc., Surgeon to the Royal Free Hospital; and REGINALD C. B. LEDLIE, M.B., B.S., F.R.C.S., Surgeon to the Miller General Hospital. Illustrated by H. H. GREENWOOD, M.B., B.S., F.R.C.S., Consulting Surgeon, G.W.R. Hospital, Swindon. London: Baillière, Tindall and Cox. 1935. Pp. 612. 7*s.* 6*d.*

IN this edition "Aids to Surgery" has been much enlarged and completely rewritten without losing its essential character of a synopsis useful to the student during the weeks immediately preceding his examination. No doubt students will continue to use it for this purpose to their profit on the appointed day. A great number of important facts have been collected in a very small compass and the illustrations are of that excellent diagrammatic nature which impresses the memory.

L'eczema du nourrisson

By Drs. M. PEHU and R. AULAGIER. Paris: Gauthier-Villars. 1934. Pp. 177. Fr.25.

THIS comprehensive review of one of the most common diseases of infancy is written on text-book lines in 14 chapters, which include a summary and a bibliography which is almost limited to French contributions to the literature. The introductory pages define the term and there follow a few brief pages on the historical aspect. Chapter 6 is particularly worthy of close study. It deals with the more serious general complications and the occasional accident of sudden death, which every dermatologist has had to record at some time or other during the treatment of infantile eczema. The authors state that in proportion to the incidence such cases are rare, but every large clinic sees them yearly, and it is strange that the mortality is actually higher in proportion among the cases admitted than in those left to take their chance in ill-equipped houses and lodging-places where the elements of sepsis and ignorance must surely be more potent than in the modern hospital ward. Some interesting experiments by Worlinger, who reproduced somewhat similar cutaneous manifestations in the course of attempts to desensitise by intradermal injections of egg albumin, are discussed, and believed to have a bearing on the incidence of the syndrome and its fatal issue. Further chapters on less immediate sequelæ, the prospect of eczema and asthma in later years, the laboratory findings, the results of food and other tests, hypotheses of the nature of the disease, differential diagnosis and the detailed treatment combine to present a rather formidable compilation. But the authors' style is pleasant and the sectional arrangement into subheaded paragraphs assists the memory and holds the attention.

The monograph omits nothing that is essential in its account of the disease, and all who read French easily will do well to read it.

THE LANCET

PEMPHIGUS NEONATORUM

OVER three hundred diseases of the skin are now recognised, and this fact alone is enough to discourage the average student from acquiring more than a superficial knowledge of dermatology. Moreover, not even the specialist can hold any brief for the existing nomenclature of skin diseases. For the most part it is fanciful, redundant, and based upon superficial resemblances rather than ætiological considerations. In addition it is very confusing, since the same terms—e.g., pityriasis, lichen, erythema, dermatitis, impetigo, and pemphigus are applied indiscriminately to entirely distinct conditions. The word pemphigus (πέμφιξ, a blister) has been employed in the past to designate a number of bullous eruptions; thus:

P. acutus, a specific infective disease due, perhaps, to a diplococcus, and met with chiefly in butchers.

P. vulgaris seu *chronicus* (with the varieties *P. vegetans* and foliaceus), a disease of unknown causation, probably infective, but certainly distinct from the above.

P. neonatorum, a bullous impetigo of the newly born, caused by the staphylococcus.

P. contagiosus tropicus (Manson), a bullous form of impetigo, affecting chiefly the axillary and crural regions, very common in certain low-lying regions of the tropics, and, according to Castellani and Chalmers, also due to staphylococcal infection.

P. congenitalis = epidermolysis bullosa, a congenital and often familial disease.

P. hystericus, a bullous dermatitis artefacta.

P. syphiliticus, the only bullous syphilide, met with on the palms and soles of congenitally syphilitic infants either at birth or a few days later.

At the present time the term is practically restricted to the first three diseases, and should in our opinion be abandoned for the first and third.

In an article published on another page of this issue Dr. POOLE and Dr. WHITTLE offer the alternative title of "impetigo contagiosa et bullosa neonatorum" for what is more generally called pemphigus neonatorum. That the eruption is clinically a variety of bullous impetigo there is no doubt, but unlike the common form of impetigo it is not caused by a primary infection with a streptococcus, but with a staphylococcus. Now staphylococci tend to involve the pilosebaceous follicles; their toxins excite a diapedesis of polymorphonuclear leucocytes, and the more virulent strains are necrogenic. The common and superficial follicular pustule, due to infection around the mouth of a follicle by the *Staphylococcus albus*, is the simplest type-lesion. The so-called impetigo of Bockhardt, better termed acute porofolliculitis, is merely an eruption of numerous follicular pustules, due in mild cases to an *albus* and in the more severe to an *aureus* or *citreus* strain. The boil is caused by a deeper invasion of a follicle by *Staph. aureus*, and is characterised by the intensity of the inflammatory reaction, and by perifollicular necrosis, which results in the formation of the core. The carbuncle is merely an agglomeration of boils accompanied by massive and diffuse tissue necrosis. The follicular involvement, the polymorphonuclear exudate, and the tendency of virulent strains to produce necrosis are thus the principal characteristics of staphylococcal invasion of the skin. Streptococci, on the other hand, have no predilection for the follicles, are less pyogenic, and tend to provoke an exudation of clear serum, containing only a few leucocytes. The initial vesicle or bulla of the impetigo of Tilbury Fox illustrates these features, and its subsequent invasion by polymorphonuclear leucocytes is doubtless attributable to the superadded infection by staphylococci, which always occurs in streptococcal impetigo.

Theoretically, therefore, pemphigus neonatorum, in which the initial lesion is a vesicle or bulla, containing at first clear serum, should be streptococcal in origin, and SABOURAUD certainly held this view. But many investigators have established the staphylococcus as the causative organism, and this is upheld by Dr. WHITTLE's own researches in eight cases of the disease. Like HAXTHAUSEN[1] he employed special media favourable to streptococci and inimical to staphylococci, but in no case were streptococci cultured. Many years ago JADASSOHN[2] described a bullous impetigo, affecting particularly the extremities, and due not to a streptococcus but to a staphylococcus, and HAXTHAUSEN has confirmed this. Moreover, BENIANS and JONES[2] noted that, when an adult was infected from handling an infant with pemphigus neonatorum, the resulting lesions tended to be of the bullous type described by JADASSOHN. They suggested that the bullous reaction of the skin, which is more characteristic of streptococcal infection, might be a response to a special strain of *Staph. aureus*. This question arises again in the rare disease, acrodermatitis continua, of which the dermatitis repens of Crocker is the localised variety. From cases of this disease a strain of *Staph. aureus* has been isolated from the skin, mucous membrane of the mouth, and from the fæces, which grew readily on media that inhibit the growth of ordinary strains. In this condition, however, the primary cutaneous lesion is a nonfollicular intraepidermal abscess, formed by infiltration of the rete with polymorphonuclear leucocytes, whereas the contents of the bullæ in pemphigus neonatorum are initially clear, as in streptococcal impetigo. In these two atypical forms of staphylococcal infection, therefore, it would seem that special strains may be responsible for the peculiar features of the eruptions. Dr. POOLE and Dr. WHITTLE agree with MCCANDLISH in regarding the exfoliative dermatitis of Ritter von Rittersheim ("Ritter's disease") as a severe and usually fatal form of pemphigus neonatorum. Since such fatal cases do occur, particularly at the beginning of of Manouvrier. This shows clearly that, while mesatiskelety gives an index of 90, let us say, macroskelety may give one of 100 and brachyskelety one of 81 or 82, but it also shows that, whereas the normal index remains practically constant during the years of puberty, the two subnormal states increase their differences. When this is taken into account with the marked changes in the development of the upper and lower parts of the thorax in these states, it seems likely that the facts possess some clinical interest; in any case they offer a clearer conception of the conditions than that presented by the rather indefinite "sthenic" and "asthenic" types of constitution of which one hears occasionally. A chapter on the little-known effects of puberty on the pigments of the eye brings to an end this important book, which will doubtless remain the classic work on the bodily facts of growth.

Occupation and Health

Vol. II. *Encyclopædia of Hygiene, Pathology, and Social Welfare.* International Labour Office. London: 12, Victoria-street. 1934. Pp. 1310. Both Vols.—£4 paper; £4 7*s.* 6*d.* cloth.

THE second volume of this compilation completes a comprehensive work, the first part of which was published in 1931. This volume deals with subjects in alphabetical order from I to Z. The headings relate to diseases, to groups of persons according to occupation, to particular occupations or to special substances causing risk to those brought in contact with them at work. Each subject is dealt with under subheadings, varying according to its nature, but, in most cases, including symptoms, diagnosis, pathology, prophylaxis, statistics, hygiene, legislation, and bibliography. Facts are drawn and instances given from all industrialised countries, so that a mass of information is brought together which cannot readily be found elsewhere. It would be too much to expect that a publication of this kind should distinguish the more from the less significant data it furnishes; discrimination must be left to the reader. Since the encyclopædia has taken several years to compile it is, of course, not completely up to date in its facts, so that it will be of less use to the specialist in occupational diseases than to those whose contact with such diseases is occasional and unofficial. Purchasers would be well advised to obtain the cloth-bound volumes, which are only 7*s.* 6*d.* dearer than the paper-bound. For a book of this size and weight even strong paper covers are unsatisfactory.

Text-Book of Surgery for Dental Students

Fourth edition. By G. PERCIVAL MILLS, M.B., B.S., F.R.C.S., Hon. Surgeon, General Hospital, Birmingham; and HUMPHREY HUMPHREYS, M.B., M.D.S., L.D.S., Hon. Surgeon, Birmingham Dental Hospital. London: Edward Arnold and Co. 1934. Pp. 342. 14*s.*

THIS book is designed to give dental students a general idea of surgery and its principles combined with more detailed knowledge of affections of the mouth and face. It is admittedly a very difficult task to review the whole of surgery in a small compass, and at the same time to avoid inaccuracies. On the whole the authors have been successful, but it is regrettable that more care was not taken in the revision of those parts of surgery which are of direct interest to the dental student. For example, the recommendation made on p. 203 and repeated on p. 241, to remove the premaxilla in the treatment of bad cases of cleft palate, is good neither from a surgical nor dental standpoint. Again, the suggestion made (p. 288) that large dental cysts which invade the antrum of Highmore after operation will become obliterated by new bone formation can scarcely be based upon observation. In other sections of the book there are misstatements, but these being outside the usual purview of the dentist, are perhaps of less importance. The work is excellently printed and illustrated.

Aids to Surgery

Sixth edition. By CECIL A. JOLL, M.S., F.R.C.S., B.Sc., Surgeon to the Royal Free Hospital; and REGINALD C. B. LEDLIE, M.B., B.S., F.R.C.S., Surgeon to the Miller General Hospital. Illustrated by H. H. GREENWOOD, M.B., B.S., F.R.C.S., Consulting Surgeon, G.W.R. Hospital, Swindon. London: Baillière, Tindall and Cox. 1935. Pp. 612. 7*s.* 6*d.*

IN this edition "Aids to Surgery" has been much enlarged and completely rewritten without losing its essential character of a synopsis useful to the student during the weeks immediately preceding his examination. No doubt students will continue to use it for this purpose to their profit on the appointed day. A great number of important facts have been collected in a very small compass and the illustrations are of that excellent diagrammatic nature which impresses the memory.

L'eczema du nourrisson

By Drs. M. PEHU and R. AULAGIER. Paris: Gauthier-Villars. 1934. Pp. 177. Fr.25.

THIS comprehensive review of one of the most common diseases of infancy is written on text-book lines in 14 chapters, which include a summary and a bibliography which is almost limited to French contributions to the literature. The introductory pages define the term and there follow a few brief pages on the historical aspect. Chapter 6 is particularly worthy of close study. It deals with the more serious general complications and the occasional accident of sudden death, which every dermatologist has had to record at some time or other during the treatment of infantile eczema. The authors state that in proportion to the incidence such cases are rare, but every large clinic sees them yearly, and it is strange that the mortality is actually higher in proportion among the cases admitted than in those left to take their chance in ill-equipped houses and lodging-places where the elements of sepsis and ignorance must surely be more potent than in the modern hospital ward. Some interesting experiments by Worlinger, who reproduced somewhat similar cutaneous manifestations in the course of attempts to desensitise by intradermal injections of egg albumin, are discussed, and believed to have a bearing on the incidence of the syndrome and its fatal issue. Further chapters on less immediate sequelæ, the prospect of eczema and asthma in later years, the laboratory findings, the results of food and other tests, hypotheses of the nature of the disease, differential diagnosis and the detailed treatment combine to present a rather formidable compilation. But the authors' style is pleasant and the sectional arrangement into subheaded paragraphs assists the memory and holds the attention.

The monograph omits nothing that is essential in its account of the disease, and all who read French easily will do well to read it.

PEMPHIGUS NEONATORUM

Over three hundred diseases of the skin are now recognised, and this fact alone is enough to discourage the average student from acquiring more than a superficial knowledge of dermatology. Moreover, not even the specialist can hold any brief for the existing nomenclature of skin diseases. For the most part it is fanciful, redundant, and based upon superficial resemblances rather than ætiological considerations. In addition it is very confusing, since the same terms—e.g., pityriasis, lichen, erythema, dermatitis, impetigo, and pemphigus are applied indiscriminately to entirely distinct conditions. The word pemphigus (πέμφιξ, a blister) has been employed in the past to designate a number of bullous eruptions; thus:

P. acutus, a specific infective disease due, perhaps, to a diplococcus, and met with chiefly in butchers.

P. vulgaris seu *chronicus* (with the varieties *P. vegetans* and foliaceus), a disease of unknown causation, probably infective, but certainly distinct from the above.

P. neonatorum, a bullous impetigo of the newly born, caused by the staphylococcus.

P. contagiosus tropicus (Manson), a bullous form of impetigo, affecting chiefly the axillary and crural regions, very common in certain low-lying regions of the tropics, and, according to Castellani and Chalmers, also due to staphylococcal infection.

P. congenitalis = epidermolysis bullosa, a congenital and often familial disease.

P. hystericus, a bullous dermatitis artefacta.

P. syphiliticus, the only bullous syphilide, met with on the palms and soles of congenitally syphilitic infants either at birth or a few days later.

At the present time the term is practically restricted to the first three diseases, and should in our opinion be abandoned for the first and third.

In an article published on another page of this issue Dr. Poole and Dr. Whittle offer the alternative title of "impetigo contagiosa et bullosa neonatorum" for what is more generally called pemphigus neonatorum. That the eruption is clinically a variety of bullous impetigo there is no doubt, but unlike the common form of impetigo it is not caused by a primary infection with a streptococcus, but with a staphylococcus. Now staphylococci tend to involve the pilosebaceous follicles; their toxins excite a diapedesis of polymorphonuclear leucocytes, and the more virulent strains are necrogenic. The common and superficial follicular pustule, due to infection around the mouth of a follicle by the *Staphylococcus albus*, is the simplest type-lesion. The so-called impetigo of Bockhardt, better termed acute porofolliculitis, is merely an eruption of numerous follicular pustules, due in mild cases to an *albus* and in the more severe to an *aureus* or *citreus* strain. The boil is caused by a deeper invasion of a follicle by *Staph. aureus*, and is characterised by the intensity of the inflammatory reaction, and by perifollicular necrosis, which results in the formation of the core. The carbuncle is merely an agglomeration of boils accompanied by massive and diffuse tissue necrosis. The follicular involvement, the polymorphonuclear exudate, and the tendency of virulent strains to produce necrosis are thus the principal characteristics of staphylococcal invasion of the skin. Streptococci, on the other hand, have no predilection for the follicles, are less pyogenic, and tend to provoke an exudation of clear serum, containing only a few leucocytes. The initial vesicle or bulla of the impetigo of Tilbury Fox illustrates these features, and its subsequent invasion by polymorphonuclear leucocytes is doubtless attributable to the superadded infection by staphylococci, which always occurs in streptococcal impetigo.

Theoretically, therefore, pemphigus neonatorum, in which the initial lesion is a vesicle or bulla, containing at first clear serum, should be streptococcal in origin, and Sabouraud certainly held this view. But many investigators have established the staphylococcus as the causative organism, and this is upheld by Dr. Whittle's own researches in eight cases of the disease. Like Haxthausen[1] he employed special media favourable to streptococci and inimical to staphylococci, but in no case were streptococci cultured. Many years ago Jadassohn[2] described a bullous impetigo, affecting particularly the extremities, and due not to a streptococcus but to a staphylococcus, and Haxthausen has confirmed this. Moreover, Benians and Jones[2] noted that, when an adult was infected from handling an infant with pemphigus neonatorum, the resulting lesions tended to be of the bullous type described by Jadassohn. They suggested that the bullous reaction of the skin, which is more characteristic of streptococcal infection, might be a response to a special strain of *Staph. aureus*. This question arises again in the rare disease, acrodermatitis continua, of which the dermatitis repens of Crocker is the localised variety. From cases of this disease a strain of *Staph. aureus* has been isolated from the skin, mucous membrane of the mouth, and from the fæces, which grew readily on media that inhibit the growth of ordinary strains. In this condition, however, the primary cutaneous lesion is a non-follicular intraepidermal abscess, formed by infiltration of the rete with polymorphonuclear leucocytes, whereas the contents of the bullæ in pemphigus neonatorum are initially clear, as in streptococcal impetigo. In these two atypical forms of staphylococcal infection, therefore, it would seem that special strains may be responsible for the peculiar features of the eruptions. Dr. Poole and Dr. Whittle agree with McCandlish in regarding the exfoliative dermatitis of Ritter von Rittersheim ("Ritter's disease") as a severe and usually fatal form of pemphigus neonatorum. Since such fatal cases do occur, particularly at the beginning of an epidemic, a study of the possible sources of infection is of great importance. This question is fully discussed by Poole and Whittle. As a rule contact of the infant with a pyococcus carrier, whether direct or by articles of clothing, is clearly responsible. A medical man suffering from impetigo of the scalp and neck noticed that in four out of the last six confinements he had attended the babies had developed *pemphigus neonatorum*, of which three died.

In considering the response to treatment it must be borne in mind that in staphylococcal as in streptococcal impetigo we are dealing with an acute infective disease. Although in both conditions suitable local treatment may, perhaps, limit the spread of infection and hasten the healing of existing lesions, it is very doubtful whether it actually shortens the duration of the attack; for recovery appears to depend on the spontaneous development of immunity to the infecting organisms. In pemphigus neonatorum it is probable that the fatal cases are doomed from the onset, and that the others recover no matter what line of treatment is adopted. This view is supported by the observations of Poole and Whittle, for they state that in the benign cases the appearance of fresh crops of bullæ suddenly ceases from 12 to 20 days after the onset, and that then rapid healing takes place. The same is true in the majority of acute outbreaks of streptococcal impetigo, and it is obviously the development of sufficient immunity to the infecting organisms that accounts for the subsidence of the attack. Moreover the authors employed five different methods of treatment and the results were much the same in each. They are to be congratulated upon their clear and convincing discussion of a potentially fatal infection. In the present state of our knowledge preventive measures are clearly of greater importance than is the treatment of the disease itself.

THE ABATEMENT OF NOISE

The annual general meeting of the Anti-Noise League was held last week in the Science Museum, South Kensington, when Lord Horder, the chairman of the League, presided over a large gathering which was addressed by the Prime Minister. An accompanying exhibition in illustration of the production of noise and its possible remedies was opened by the Prime Minister and must bring before the public and the medical profession both the serious nuisance with which the public puts up through the prevalence of noise, and the many practical steps which can be taken to abate that nuisance. The League has published an official handbook surveying many aspects of the problem, and to this the chairman of the League supplies a brief preface in which he assumes that the nuisance of noise as a disturber of human happiness has been generally accepted—a point which is shown by the fact that needless noise is already being suppressed wherever possible. But the range of possibility must be extended, for the amount of noise which remains to be got rid of is very great. The directions in which further measures can be taken are indicated in the handbook, whose contents call for earnest attention. Grumbling at the additional burden to life inflicted by noise is widespread; the League exists to give practical effect to that grumbling by securing effective remedies.

What amount or character of noise can be made without an offended public or individual having the right of redress against those responsible for its origin is rendered hard to determine through the fact that there is no legal definition of nuisance; but Mr. H. G. Strauss, K.C., by setting out cases where injunctions have successfully been obtained, helps us to appreciate what very considerable relief may exist if the public realised its powers, and also the very real menace to health brought about by needless din. Air Vice-Marshal Sir David Munro, secretary of the Industrial Health Research Board, describes in the handbook two experiments carried out by the Board which went to show that the reduction of noise intensity effected by using ear defenders was accompanied by an increase in the efficiency of the workers of about 8 per cent. As in these experiments the good effect was found to be neither temporary nor to occur only in individuals when first exposed to a noisy environment, but was shown to exist among those who had for years been accustomed to excessive noise as a normal accompaniment of their work, it follows that the tolerance of excessive noise may never be completely acquired, and that those who dismiss the possible damage to workers and work in factories with the facile consideration that "the men are used to it," will have to revise their opinion. These experiments were dealing only with an excessive noise of a sort to which the public is not exposed, but Wing-Commander T. R. Cave-Browne-Cave, professor of engineering, University College, Southampton, writing on noises caused by motor transport, approached the subject at a point which concerns us all. We learn, as the result of an inquiry initiated in the *Times* by Sir Henry Fowler, chairman of a special committee of the British Association appointed to consider the question, that the noises which try the public most are those caused by motor bicycles and inadequately silenced cars, the humming of aircraft being also frequently complained of. The subject of mechanical silencing is discussed in considerable detail by Prof. Cave-Browne-Cave, who shows two very satisfactory things, that effective silencing is more easily obtained than the noise in our streets would have led one to suppose, and that manufacturers are on the alert, and are ingenious and anxious to put down noise. The last is amply proved by the display in the exhibition of numerous effective appliances for bringing about the quiet running of machinery, subduing the reports of exhaust and other noises associated with motor traffic, and mitigating noise within buildings.

The Prime Minister, in addressing the meeting, was eloquent in a diatribe against the callousness and vulgarity which sanctioned the production of much of the noise amidst which we live, while Sir Henry Richards, chairman of the executive committee of the League, brought the question more closely within medical range by stressing the

.in and evil influences which invalids and children cur through being subjected to perpetual noise. nd if noise exercises deleterious influences upon lult and industrial workers, how much more must have evil repercussions upon the sickly, the licate, and the young ? It is right to remember at the young love making a noise, and Lord ORDER has pointed out that it is unkind to ppress this natural instinct ; he would allow the illest use of the lungs and the loudest and shrillest ys in the nursery or in the playing field. But ese are not the places where the invalid tries to st or the child to sleep. The arguments in the andbook published by the Anti-Noise League, and e devices brought together for consideration in e exhibition on view for the next month at the cience Museum, should secure for the League wide upport in its attempts to stamp out needless oise. The law has shown itself sympathetic, and gislation will surely follow upon public demand uch as the League will organise.

THE PHYSIOLOGY OF THE FŒTUS

IT is usually taken for granted that the specific unctions of cells are in abeyance when they are ndergoing growth or proliferation. It is not urprising, therefore, that our knowledge of fœtal physiology is that of the development of the various organs rather than that of the work which they actually perform. Prof. J. BARCROFT and his colleagues during the last few years have shown that the reverse side of the picture is by no means a blank. They are beginning really to understand the respiration and circulation of the fœtus. Their earlier observations were reviewed by Prof. BARCROFT in our columns two years ago[1] and in the Croonian Lecture which he gave before the Royal Society last month he was able to add the considerable results since obtained.

The elaborate technique of experimental physiology has here amply justified itself by revealing the apparent anomalies which gave rise to these investigations. Measurement of fœtal blood flow and oxygen usage had been attempted by previous workers without much success, but of recent years more consistent measurements have been obtained, notably by the Cambridge school. They have been able to show conclusively, in the goat, that if the hæmoglobin of the fœtus and the hæmoglobin of the mother had the same properties, and if oxygen could only pass from one to the other across the placental membrane by diffusion, the fœtus could not possibly obtain sufficient oxygen to maintain life during the latter part of pregnancy. The only way in which the mother can ensure an increasing oxygen-supply to the fœtus is by increasing the volume of the blood passed through the placenta in unit time and keeping this blood as fully oxygenated as possible. Owing to the fact that the fœtus grows in size at a much greater rate than does the placenta, and by its increased blood flow abstracts the maximum amount of oxygen from the maternal blood, these maternal mechanisms must inevitably break down. How then is the life of the fœtus preserved ? A study of the oxygen dissociation curves of fœtal and maternal hæmoglobin shows that in most animals the maternal curve is depressed and moved to the right, while the fœtal curve is moved to the left. This means that at a given pressure the available oxygen will distribute itself in unequal volumes between the two hæmoglobins, the fœtal taking the greater share. The less the actual tension of oxygen the more marked is this disparity in distribution. There is yet much work to be done concerning the nature of this difference between fœtal and maternal blood. The maternal hæmoglobin does not actually change, but its properties are modified by the diminution in alkali reserve which takes place during pregnancy. Fœtal hæmoglobin, on the other hand, shows definite but perhaps chemically slight differences from that of the adult, and these differences are of very great physiological importance. The nature of the conversion after birth of the fœtal type of hæmoglobin to the adult type remains undetermined, but raises interesting questions with regard to the storage of iron during this stage, and the occasional occurrence of icterus neonatorum. We must be cautious, however, in transferring these results uncritically from animals to man, for in his Croonian Lecture Prof. BARCROFT states that the affinities of the human hæmoglobins are themselves reversed, although the properties of the bloods assume the same relationship as in other animals when the hæmoglobin is in its normal form enclosed in corpuscles.

Another noteworthy contribution to the physiology of the fœtus, very much bound up with the foregoing, is the confirmation by physiological methods of the crossing of the blood streams in the right auricle, the arterial blood from the placenta being diverted to the head region, and the venous blood returning from the head being directed back to the placenta and the lower part of the body. It is significant that the liver receives the fully arterialised blood first, even before it gets to the heart, and that the " head " is much more extensive than was at one time believed. The arterialised blood from the aortic arch actually finds its way to all the thoracic part of the body, and to nearly the whole of the spinal cord. Most of the important parts of the body, therefore, receive truly arterial blood, although their requirements of oxygen are modest. This is largely explained by the lack of any necessity for heat production in the fœtus, and the absolute flaccidity of the muscles. So long as the experimental fœtus is kept in a warm bath, electrical records show no action currents revealing " tone " in the muscles, but such currents begin directly cold air gains access to the skin. There is, of course, a certain amount of " spontaneous " muscular movement which is probably reflex in nature, reflexes originating in cutaneous stimuli having been shown to be well established half-way through pregnancy ; but the oxygen usage just before birth is only about one-fifth of that immediately afterwards. We look forward with confidence and interest to the extension of this work, already assuming concrete form in many directions. It has opened up a practically virgin soil, which has been cultivated with much ingenuity.

---

ANNOTATIONS

THE BIRTHDAY HONOURS

As is appropriate for a year of jubilee, the list of honours conferred by the King on his birthday last Monday is an unusually long one. The names set out on p. 1358 represent many kinds of work in many kinds of place, and there is unbounded effort and service behind them. The list as a whole reflects the very proper tendency towards wider recognition of work done in official positions—work which is otherwise too often taken for granted. There are some names, however, which represent achievement mainly or altogether outside public office, and first among these stands that of Sir Gowland Hopkins, president of the Royal Society, who is granted the highest possible distinction in membership of the Order of Merit. On retirement from his many years at the Board of Education and the Ministry of Health, Sir George Newman is made a knight grand cross of the Order of the British Empire; while in the Royal Victorian Order, associated with personal service to the Royal Family, Sir Cooper Perry becomes a knight grand cross, and Mr. Walton and Mr. Barrington-Ward knight commanders. Among other new knighthoods two in particular are for "freelance" service—those of Prof. Arthur Hall and Dr. P. P. Laidlaw, F.R.S. Dr. Hall's honour is granted for fine contributions to medicine with special reference to the health of industrial workers, while Dr. Laidlaw, after years of fruitful investigation both in physiology and pathology, has, with his collaborators at the National Institute of Medical Research, achieved the prophylaxis of distemper in dogs and has recently had striking success in the study of influenza. Outside the stricter confines of medicine there are several other new knights whom we may gladly mistake for members of the medical profession. Prof. Joseph Barcroft (who holds, indeed, an honorary medical degree from Louvain) has done much to increase the fame and usefulness of the Cambridge physiology school, and the medical implications of his work are brought out on the preceding page; Mr. L. J. Brock has won a high reputation by his work as chairman of the Board of Control; and Prof. J. C. M'Lennan, the Toronto physicist, has given valuable assistance in this country to those responsible for the allocation and use of radium.

THE VOLUNTARY HOSPITAL PRINCIPLE

At the annual conference of the British Hospitals Association held at Leamington last week, the possibility of maintaining the voluntary hospital system was discussed in a paper presented by Lord Cozens-Hardy and Mr. C. A. Wells, respectively chairman of the Liverpool Hospitals Commission and assistant surgeon to the Royal Southern Hospital, Liverpool. Public support for voluntary hospitals, said Lord Cozens-Hardy, had never been more generous than to-day, but the Local Government Act of 1929 had plainly threatened the very existence of the voluntary hospital system. The proper and indeed the only possible answer in his opinion was to make the system so strong, efficient, and attractive that its essential characteristics would be left unchanged; to ensure this some machinery must be provided through which voluntary hospitals could speak with one voice and coöperate with public authorities, and this implied a speedy amalgamation of too numerous units and the preparation of a considered programme. It was pointed out in discussion that the London County Council had set an example of efficiency in standardisation and group-buying for hospitals which the voluntary hospitals could not pretend to equal, and this example must be followed without delay. The house governor of one of the principal Birmingham hospitals said that the position in Birmingham was as complicated and difficult as in Liverpool, and he urged the conference to concentrate on the larger centres. The single hospital area at the moment was made relatively safe by a local patriotism unknown among the larger groups. A representative of the Ministry of Health assured the conference of the benevolent interest of the Ministry in the voluntary hospitals and agreed that Lord Cozens-Hardy's proposals if carried out would greatly lighten the task of the Ministry. At the conclusion of the conference a statement was issued announcing the setting up of a commission of inquiry to investigate the position of the voluntary hospitals of this country. The reference of this commission is "to take into consideration the present position of the voluntary hospitals of the country; to inquire whether, in view of recent legislative and social developments, it is desirable that any step should be taken to promote their interests, develop their policy, and safeguard their future; and to frame such recommendations as may be thought expedient and acceptable."

RESEARCH IN RADIOLOGY

The report of the *National Physical Laboratory*[1] is a record of routine testing and of research carried out at Teddington during the past year. On the radiological side there has been remarkable expansion and the section of the report written by Mr. G. W. C. Kaye, D.Sc., superintendent of the physics department, contains much of interest to the medical radiologist. During the year the Teddington laboratory, in association with similar institutions on the Continent and in America, prepared a memorandum on X ray units and standardising procedure, which was adopted by the International Committee for Radiological Units at Zurich. The measurement of X rays in international r units has been facilitated by the development at the laboratory of a direct reading instrument for this purpose. Further investigations have been carried out on X ray protection as a result of which data are now available from which the degree of protection from X rays required in various circumstances may be readily computed. This department has tested protective materials and inspected the X ray equipment in use in a large number of hospitals in London and elsewhere. The national radium standard has been exchanged for a new one of exceptionally pure anhydrous radium chloride. A comparison of the old and the new standards by a gamma-ray method carried out at the laboratory showed that the radium content of the old standard agreed to within 3 parts in a thousand with the original certified value, after allowing for radio-active decay during the period 1912–1934. Nearly 12 grammes of radium in some 1700 containers have been submitted to the laboratory for measurement during the year. Periodic leakage tests of containers which are in regular use and minor repairs have been carried out on behalf of various hospitals. The measurement of the content of radium needles by the gamma-ray method necessitates the use of a correction for the absorption of gamma rays in the walls of the needles. As a result of further research, more accurate absorption corrections have been obtained for tubes of platinum and monel metal. The protection of those engaged in radium therapy has been the subject of further study and experiment. Two factors of gamma-ray protection have been studied—viz., remoteness and lead-shielding in a variety of routine circumstances. As a result the minimum shielding and the tolerance working distance have been determined under the various conditions commonly met with in radium therapy. A development which will be watched with interest is the application of X ray crystallographic methods to the study of tooth structures. A technique has been developed for obtaining X ray diffraction patterns directly from the surfaces of teeth. This study, the report states, is still in the preliminary stage, but the results already obtained are encouraging.

TROPICAL MEDICINE IN CHINA

THE first volume of the Transactions of the Far Eastern Association of Tropical Medicine held in Nanking, China, in October, 1934, has already been reviewed in these columns, and now a second equally stout and well-documented volume has followed hard on its heels. This volume, edited with no less assiduity, consists of some 100 papers on such diverse subjects as malaria, medicine, ophthalmology, parasitology, pathology, pharmacology, physiology, plague, public health, quarantine, radiology, and surgery. Under the heading of malaria extensive researches upon treatment (notably with atebrin) and on the prevention of the disease are published. C. D. de Langen and C. J. Storm have written on the modern medical treatment of malaria, from the department of internal medicine of the Medical School of Batavia, Java, where they have enjoyed the collaboration of a physiologist who has recorded the ventricular tracings of the heart and cardiographic curves in monkeys treated with quinine, plasmoquine, and other antimalarial drugs. A. L. Hoops has made a series of observations on the prophylaxis and cure of malaria with atebrin on Malacca Rubber Estates; his experiences have been extremely favourable to the drug.

In the medical section H. S. Gear and H. Pedersen contribute an informative study on diseases common to man and animals in China, which appears to swarm with parasites of all kinds. T. Y. Li and H. Gordon Thompson write on the treatment of *Schistosomiasis japonica* with antimony compounds; they see no reason to doubt the generally accepted view that potassium antimony tartrate is the best method of getting rid of this parasite. Dr. T. S. Kwa has made a study, illustrated by radiograms, of lead encephalopathy in Chinese children, in which the children have been poisoned by their mother's milk; the onset is apparently encouraged by a state of avitaminosis. There are three papers on beri-beri as it occurs at present in China, and it is evident from the work of Y. Y. Ying that this disease is apt to supervene as an important complication in typhoid fever. Teodulo Topacio, of the Bureau of Animal Industry, Manila, has devised a method of transmission by a single trypanosome.

In the section of pharmacology B. E. Read has made a historical investigation of the newer pharmacology and its relation to ancient medicine. Dr. H. A. Bor and Dr. C. J. Storm write of a clinical and experimental investigation of evipan-sodium anæsthesia. Lt.-Col. A. J. H. Russell contributes a paper on plague in India, in which he shows that the plague mortality in that country during the five-year period from 1898–1933 totals over twelve million deaths. To the section of surgery J. Gray and H. Gordon Thompson have contributed a readable paper on surgical complications of parasitic diseases, and the volume ends with a series of papers upon vesical calculus amongst the Chinese. The fact that these transactions have appeared within a few months of the congress adds to their interest.

DIAPHRAGMATIC HERNIA

WE have already drawn attention[1] to the symptoms which, when confirmed by radiological evidence, often enable a diagnosis of diaphragmatic hernia to be made with some confidence before operation. Sir Thomas Dunhill, in an Arris and Gale Lecture delivered before the Royal College of Surgeons,[2] has given an account of 25 patients suffering from various types of this condition, on 6 of whom he has successfully operated. He draws the conclusion from his records that the symptoms in a case of diaphragmatic hernia strongly suggest their origin; and that, when the patient has an œsophagus of normal length, operation is able to cure the distressing symptoms, and usually carries with it a risk less than that inherent in the disease. Unfortunately the commonest type is that associated with a short œsophagus, the cardia being situated some distance above the œsophageal orifice in the diaphragm; 14 of Dunhill's cases were of this nature, and for such cases no radical cure has as yet been planned. The proportion of "diaphragmatic herniæ" which are really attributable to a short œsophagus is so high that it may constitute a pitfall for the radiologist. In one of Dunhill's cases the original diagnosis was "short œsophagus." A lateral X ray picture, however, showed an œsophagus of normal length lying behind the stomach, a large part of which was situated in the posterior mediastinum. Complete relief of the very pronounced symptoms followed withdrawal of the stomach from the thorax and closure of the gap. Had the original X ray diagnosis been accepted, the patient would never have been given the chance of operation. The short œsophagus is, in Dunhill's opinion, a definite failure in development, and a cause of symptoms which tend, once they have appeared, to be progressive. It is not to be dismissed as a mere extension upwards of the gastric type of mucosa. Hydrostatic pressure from below, and the suction effects of inspiration, tend to increase the herniation of the stomach, while distension of the thoracic loculus and rotation of the stomach on its long axis may easily kink the œsophagus and may cause pressure effects on the pericardium. Cardiospasm also tends to occur, and in some cases there is an organic stricture of the œsophagus; gastric ulceration has also been reported. The causes of dysphagia and of thoracic pain and oppression are thus numerous, and the reasons for the progression and inconstancy of the symptoms explained.

In the short œsophagus type of hernia, and in para-œsophageal hernia, as described by Prof. von Bergmann, Dr. A. F. Hurst,[3] and others, there is no developmental defect in the diaphragm. In the other types of diaphragmatic hernia, failure either of the normal process of closure of the pleuroperitoneal canal, or of muscular transformation of the membranous diaphragm can be recognised. In the process of muscularisation, Dunhill points out, the crura are last to develop, and he believes that non-development of one or of both crura is an important cause of hernia. Thus, although he allows that hernia at the costovertebral angle in infants is probably due to a persistence of the pleuroperitoneal canal, in adults a definite sac is present, illustrated in each of the three cases which he himself describes, and his impression is that congenital absence of the left crus of the diaphragm is the underlying cause. Congenital non-development of both crura accounts for the type of hernia which, as mentioned above, may be mistaken for a short œsophagus. There is no attachment of the diaphragm posteriorly in the region of the aorta and œsophagus. As might be supposed, a satisfactory operative closure of the defect is not easy; but, nevertheless, this operation has had much clinical success. Herniæ through the retrosternal attachment of the diaphragm and through a defect in the left dome of the diaphragm were found in three other cases, in two of which operation was successfully performed.

[3] Guy's Hosp. Rep., 1934, lxxxiv., 43.

The symptoms in these cases are related either to the obstructive effects on the gastro-intestinal tract, or to pressure on the thoracic contents. Thus, in some cases the main complaint is of a sensation of bursting and of tightness and pain across the chest; in other cases, indigestion, vomiting, or hæmatemesis predominates. It is not unusual for both types of symptoms to be associated, and the patient may be actually afraid to eat, though badly wanting food, or be unable to turn over comfortably in bed. It is important to recognise that in herniæ through a large diaphragmatic defect, in which there are no adhesions, the abdominal contents enter the sac only at intervals and may be completely absent from the thorax at the time of radiological examination, or at operation; where the abdominal return of the organs is obstructed, the condition of thoracic herniation, once it appears, must be progressive. In cases which are inoperable a certain amount of relief may follow the use of a stomach pump or the passage of a bougie.

THE DENTAL SIGN

OPENING the twenty-eighth session of the Dental Board of the United Kingdom Sir Francis Dyke Acland spoke of the exhibition of signs as a means of notification of dental practice. The Dental Board, he said, had been in touch with the British Dental Association, the Incorporated Dental Society, and the Dental Public Service Association in the matter; representatives of all these organisations had expressed agreement with what he believed to be the policy of the Board. Sir Francis then restated in a few words the principles of this policy. "We try," he said, "to pursue not a static but a progressive policy; one cannot bring everyone in every place up to exactly the same standard at any given time. But a great many signs have in some places (particularly seaports or commercial centres like Hull, Newcastle-on-Tyne, and Dundee) habitually, and in other places sporadically, been beyond what is necessary for reasonable notification of the place of practice; and the Board are bound to pursue progressively attempts to secure improvement. New entrants to the profession, therefore, will be well advised to realise that it is unwise to assume that the most conspicuous signs which they can find already being exhibited by any of their fellow-practitioners in their district at the moment can safely or properly be accepted as setting the standard of what they should themselves exhibit." Sir Francis went on to express a hope that friendly agreement would be reached between the Board and the dental organisations about the means to be adopted for effecting improvement. The British Dental Association had, he said, conducted a survey recently in which definitely undesirable matters were reported, e.g., a dentist in Dundee with five large plates, a lettered lamp, a V-shaped sign with 4-foot sides, and four window signs; in Newcastle-on-Tyne a dentist with a plate, a door sign, a fanlight sign, and three window signs. It is likely that a joint advisory committee will be formed so that agreement may be reached on the action which ought to be taken—in the first instance in certain specific districts. It is essential, Sir Francis added, that exactly the same standard be observed with members of dental organisations as with non-members and that the action taken in any place should be simultaneous.

THE NATURE OF TUBERCULIN

LAST year S. R. Douglas and P. Hartley found[1] that even after autoclaving and prolonged heating at high temperatures solutions of old tuberculin retain not less than half of their original activity. The practical importance of the physical properties of tuberculin are brought out in a recent note[2] by H. J. Parish and R. A. O'Brien. Not only does tuberculin survive autoclaving, but it clings to glass and is not removed by ordinary washing. There is therefore considerable danger of misleading reactions if syringes which have been used for the injection of tuberculin are later used for other purposes. This stability to heat of tuberculin raises the question of its chemical nature. It has generally been considered to be a protein, and F. B. Seibert in 1928 described[3] its preparation as a heat-coagulable protein free from all except traces of carbohydrate. However when such preparations were coagulated by heat a certain amount of activity remained in the uncoagulated portion. A more recent paper[4] by the same author gives an explanation. The molecular weight of active protein prepared from unheated tuberculin is about 24,000, or rather less than that of egg albumin, while that of the preparation from heated tuberculin is from 2000 to 4000. The smaller molecules still give the specific tuberculin reaction, although they are no longer antigenic in the sense of producing antisera on injection. It appears that when tuberculin protein is heated it not only undergoes an internal rearrangement resulting in insolubility, as do proteins such as egg albumin, but also breaks up into smaller molecules. The specific activity resides in relatively small groups of amino-acids which resist disruption.

PNEUMONIA AND DIGITALIS

SOME years ago the statement was made that "the routine giving of digitalis to patients with lobar pneumonia is dangerous."[5] Cohn and Lewis[6] preface their inquiry into this controversial subject by reviewing the statistical method by which this conclusion was reached, namely, the "alternate control system." This system, they agree, is valid so long as the number of cases is sufficiently large, but they reject it as unsuitable for the present purpose in view of the variations in pneumococcal virulence over a period of years and in human susceptibility. Failing a sufficiency of material they prefer an analysis and comparison based on "severity of the disease," and this has involved a preliminary decision as to what should be regarded as unfavourable factors in the course of the disease. The following eight factors have been selected as having an influence on the outcome of pneumonia: type of work (light or heavy); type of pneumococcus; age (above or below 40); alcoholism;

bacteræmia; number of lobes involved; cardiovascular affections; and complications. The graphs illustrating the effects of each of these upon mortality are interesting, but, as Cohn and Lewis emphasise, it is usually necessary in practice to consider the effect of several factors at once, and it is doubtful how far their representation conveys a fair impression when the same importance (i.e., unity) is attributed to each. Nevertheless the graphic method does bring out the fact (scarcely unexpected) that mortality increases with the number of unfavourable factors, and it shows a sharp rise in the death-rate when three or more of those enumerated are in operation. That these eight conditions are the ones that really matter in determining prognosis is further indicated by the statement that "when none of the untoward factors was present death was rare, there being only two deaths among 288." A laborious investigation to find whether any particular combination of the eight was particularly harmful yielded no significant results.

Having thus cleared their ground, Cohn and Lewis come to digitalis in pneumonia and begin by stating the known facts—that digitalis acts upon the heart, that its therapeutic value is most evident in auricular fibrillation, that it acts upon the febrile heart, and that it depresses conduction of the cardiac impulse in pneumonia. It is rare to find auricular fibrillation as the *only* untoward factor in the illness, but the investigators feel justified in saying, first, that the chances of those who have it are not worse than those of other patients, and secondly, that digitalis has proved useful when not more than two untoward elements (other than fibrillation) have been present. "When there were more untoward elements, the chances were not worse than they would otherwise have been." Admittedly cautious, these conclusions, based on careful analysis, deserve consideration alongside the statement with which this annotation began—though, as Cohn and Lewis point out, the discrepancy may be due to differences in the methods of investigation. So far as they go, the results of the inquiry suggest that in practice digitalis does not influence the course of lobar pneumonia, except in otherwise favourable cases showing fibrillation or flutter.

ARTIFICIAL SEX HORMONES

THE chemistry and artificial preparation of the gonadal hormones has lately been reviewed by Prof. Butenandt in a lecture given in Berlin,[1] which, especially when it is compared with one he delivered last summer,[2] gives a striking impression of the speed of advance in this field. Gonadal activity can now be accounted for in both sexes by chemically pure, crystalline substances of settled constitution which have been isolated from urine or from the organs themselves. The male hormone is represented by androsterone—isolated first from urine by Butenandt, and recently prepared artificially from cholesterol by the method of Ruzicka—and by "dehydroandrosterone" and "dihydroandrosterone." The œstrogenic hormone is represented by œstrone, œstriol, and œstradiol; the last compound, first prepared by reduction of œstrone, has now been isolated from ovaries by Doisy and his collaborators,[3] and is the most active of the three. The isolation of the corpus luteum hormone from sows' ovaries was announced by four groups of workers last year, and now two methods of artificial preparation from other, more readily available, natural products are known. All these compounds are derivatives of what may be called the steroid nucleus—i.e., they contain the carbon skeleton of *cyclo*pentenophenanthrene common to the sterols and bile acids.

Two tasks remain to complete this scheme of isolation and synthesis. First, there is reason to doubt whether the urinary product androsterone accounts for the whole activity of the testis,[4] or even of crude urine extracts,[5] and laborious efforts to isolate a simple product from testes have so far failed. Secondly, an artificial preparation of œstrone has not yet been achieved, although Honigmann [6] has obtained from ergosterol an active product which resembles equilenin, one of the œstrogenic compounds in mare's urine, but which still has the sterol side-chain attached. It is not likely to be long before the chemistry of the gonadal hormones is completed in these particulars.

IODINE AS A PREVENTIVE OF GOITRE IN MAN AND ANIMALS

FROM time immemorial goitre has been treated by the administration of burnt sponge, but it was not until 1812 that a saltpetre manufacturer discovered iodine in the ash. A few years later Coindet made what Prof. Harington in his Oliver-Sharpey lecture (THE LANCET, May 25th, p. 1200) called his "inspired guess" that the newly discovered element was the active principle of the traditional remedy. This was followed by Chatin's demonstration, which failed to convince the Paris Academy, of a relationship between endemic goitre and environmental deficiency of iodine. The connexion has now been so widely substantiated that, in Prof. Harington's words, "with the possible exception of certain cases in New Zealand, there is no region where goitre is severely endemic in which it has not been possible to demonstrate an environmental deficiency of iodine." Coindet and his immediate followers employed iodine therapy as a curative measure only, but it is now being widely used as a prophylactic, and the International Office of Hygiene published in its monthly bulletin for April the answers to a questionnaire addressed to countries which are in the habit of distributing iodised salt or iodised sweets as a preventive of goitre. The questions were designed to elicit information on the composition, preparation, and presentation to the public of iodised salt or sweets. Replies were received from Germany, Italy, the Netherlands, Sweden, Switzerland, the United States of America, and Yugoslavia, and they are characterised by a considerable measure of agreement.

Practically all the countries adopt the proportion of 10 milligrammes (mg.) of iodide of potassium to one kilo of salt in their preparations, but in Switzerland the dosage is only 5 mg. All the authorities recommend that iodisation should be carried out after the salt has been crystallised and dried. Where it should be done depends somewhat on the source of supply, but, generally speaking, it is considered advisable to add iodide of potassium to ordinary household salt at the factory or warehouse, and to pack it as quickly as possible. America and Switzerland both give a warning against using unduly large containers. In America it has been found that it is possible for the iodine to become separated, and the Swiss report states that the iodine is apt to sink, so that after some lapse of time the top layer may contain only 3·5 mg. and the lowest as much as 6 or 7 mg. per kilo, the middle layer retaining its original strength. This is an indication that iodised salt should not be left long in bulk before being packed.

[6] Honigmann, H.: Liebigs Ann., 1934, dxi., 292.

The method of packing and distribution is important. All the references to this matter agree in rejecting glass bottles, chiefly on the score of expense. In the Netherlands the iodised salt is packed in parchment bags enclosed in cardboard; in Yugoslavia it is distributed in the same way as ordinary salt, in bags of jute or canvas; Germany finds paper bags enclosed in boxes with compartments preferable to cloth or canvas; America and Switzerland consider cardboard boxes the most suitable, as being practically impermeable to the air, America stating that iodised salt is apt to lose weight when packed in paper or cloth.

In most cases iodised salt is used as a prophylactic only. In Italy it is distributed to the whole population instead of ordinary salt in certain districts subject to endemic goitre, no inconvenience having been suffered from its use. Where iodised salt is not employed iodine is given in the form of chocolate tablets, but this is looked upon as incomplete because it is impossible to distribute sweets to the whole population. In the Netherlands iodised salt is regularly administered as a prophylactic in districts where drinking water or articles of food are deficient in iodine. There is considerable diversity of opinion as to the desirability of giving iodine in the form of sweets. Germany and the Netherlands are definitely unfavourable to this type of treatment, being of the opinion that there is danger of overdosage. Switzerland makes use of iodised salt only as a preventive, but sweets containing Iodostarin—an organic compound of iodine—are used both for prophylactic and curative purposes. One sweet a week, containing 1 mg. of iodostarin, is given as a prophylactic to school-children and military recruits, and sweets containing 3 mg. of iodostarin are used curatively. The report recommends that iodised sweets should not be on sale except under medical direction. Swedish school-children at Hofors who show no signs of goitre undergo a short course of treatment with iodised sweets every spring and autumn, one sweet a day being given for ten days. This is equivalent to a dosage of 4 grammes of iodide of sodium a year. The only inconvenience noted is an occasional transitory cold in the head, and doctors report that goitre is much less frequent among the children of Hofors than formerly. In America iodised salt is only recommended for the prevention of simple goitre. Speaking generally, the idea of iodised sweets has been abandoned, but in New Jersey chocolate tablets containing 5 to 10 mg. of iodine are given to children once a week all the year round.

The closely related problem of insufficient iodine in the breeding of livestock is dealt with in an interesting brochure by Mr. Frank Corrie, B.Sc., issued by the Nitrate Corporation of Chile, Limited. In our own columns recently (May 4th, p. 1029) Dr. Donald Hunter has alluded to the danger in certain parts of the world of animals failing to secure enough iodine in their food. In the Yellowstone River valley numbers of young pigs, lambs, calves, and colts used to die as the result of thyroid disease, and this calamity was averted when the shortage of iodine in the soil was made up for by giving sodium or potassium iodide to pregnant animals. Later the same problem arose in the Pemberton valley of British Columbia, where white settlers noticed as they ascended the valley that the incidence of goitre and fœtal athyrosis increased in their animals. Poultry appeared to thrive, but their eggs though producing embryos failed to hatch out. All goitres disappeared and no further trouble in rearing stock or fowls occurred after iodine was added to their ration. For two dollars a year sufficient iodine could be procured to keep 100 cattle, 12 horses, 30 pigs, 200 chickens and all their progeny free from goitre. Mr. Corrie summarises the experience of practical stock-breeders, with many of whom he is in correspondence. There is no doubt, he says, that even in many districts of this country the iodine content of the soil is inadequate to provide growing crops with a sufficiency of iodine to meet the requirements of stock. The artificial foods now so commonly used contain, he suggests, too little iodine to meet the needs of highly productive animals. Guano or Chilean nitrate of soda may help, but the judicious use of iodine in feeding stock is the best and cheapest form of insurance policy for the breeder. Mr. Corrie recommends a stock solution made by dissolving three-quarters of an ounce of potassium iodide in seven pints of water. Of this solution the daily ration for a horse is three teaspoonfuls, for a pig two, for a goat one, for a dog a quarter, for a rabbit one-twentieth; and much evidence is set out in the pamphlet, with abundant illustration, to show that these doses are effective.

BUSTS OF KOCH AND RÖNTGEN

THE Deutches Museum in Munich celebrated[1] last month the tenth anniversary of its foundation, and opportunity has been taken to place busts of Robert Koch and Konrad Röntgen in the chamber of honour. The bust of Koch which is by Prof. Georg Müller bears the inscription: "The discoverer of the tubercle bacillus and of other disease producers. In strict logical sequence he showed the ways to effective attack on the diseases that plague mankind." The dedication was made by Ministerial Director, Dr. Gütt. The twenty-fifth anniversary of Koch's death on May 27th has given another German medical weekly[2] occasion for an assessment of his work by the director of the Robert Koch Institute in Berlin. It was Koch, says Dr. Gundel, whose revolutionary genius let in the light to the causes and method of spread of infectious disease. The bust of Röntgen by Prof. Hermann Hahn was presented to the Munich Museum by Prof. Harms in the name of the University of Würzburg; the inscription runs: "The rays which bear his name show the physician the interior of the living body; they show the engineer the interior of his working materials; they have given the scientist a knowledge of the inner structure of the atom." The German Chemical Society proposes to present to the Museum memorial busts of F. Wöhler and Adolph v. Baeyer.

THE Ingleby lectures of the University of Birmingham will be given by Dr. K. D. Wilkinson, professor of therapeutics in the University, on Thursdays, June 13th and 20th, at 4 P.M., in the medical lecture theatre, Edmund-street. The subject is acute rheumatism and its results, and members of the medical profession are invited.

IT is proposed that a two-day conference shall be held at the London School of Hygiene and Tropical Medicine each July, so that medical officers in industry on leave from the tropics may be able to meet their colleagues and discuss their problems. Medical officers practising on plantations, mines, railways, hydro-electric and construction schemes, and development companies generally, will be welcomed. This year the conference will be held on July 9th and 10th. Those who intend to be present should write to the organising secretary, Ross Institute of Tropical Hygiene, London School of Hygiene and Tropical Medicine, Keppel-street, W.C. 1.

PROGNOSIS

A Series of Signed Articles contributed by invitation

LV.—PROGNOSIS IN DIPHTHERIA

Diphtheria although a preventable disease still ranks in this country as one of the formidable acute specific infections of childhood. Owing to the greater opportunities for infection, the highest incidence of the disease occurs shortly after school age, but the maximum case mortality, which at all ages is some 5 per cent., falls upon those of pre-school age. The age of the patient is therefore an important factor in prognosis. Clinical diphtheria, as distinct from a carrier state, implies the formation of pseudo-membrane by virulent strains of the *C. diphtheriæ* and a varying degree of toxæmia. There is considerable evidence of the frequent association of the *gravis* (starch fermenting) and *intermediate* (barred) strains of the bacillus, described by Anderson, McLeod, and their co-workers, with diphtheria of severe clinical type; but these strains are not invariably causal of severe attacks nor are those due to the *mitis* strain consistently mild. Generally speaking, however, gravis and intermediate infections tend to produce severe clinical attacks with rapid advance of toxæmia. Since diphtheria antitoxin adsorbs circulating toxin, checks the further spread of membrane (upon the extent of which toxæmia depends), and influences its early separation, prognosis is largely dictated by the promptness with which an adequate dose is injected by a route which is also adequate in the particular circumstances. Antitoxin can only prevent *further* damage by toxin; it cannot undo damage already brought about. Therefore the success of antitoxin therapy must depend primarily upon early diagnosis. This in turn depends not only upon the clinical judgment of the practitioner but upon the stage at which he is permitted to exercise it. The prognosis may have become virtually hopeless before medical aid is sought. Nevertheless, be the patient seen early or late, the existence of membrane, however indefinite or merely "suspicious," in the one case, or however old and necrotic in the other, should imply, without exception and without delay, the administration of antitoxin. But whereas in early cases a moderate dose by the intramuscular route ensures a favourable prognosis, in later ones the only chance of converting "grave" into "less grave" may be the injection of a massive dose intravenously. Here further damage must be stemmed, not after a further delay of 8 to 12 hours, which the intramuscular route imposes before there is effective concentration in the tissues, but immediately. Adequate dosage is essential; but an adequate dose injected by an inadequate route in the critical case may improve prognosis but little if at all. Swabbing, if allowed to usurp the place of clinical judgment, is a definite factor in increasing the gravity of prognosis in diphtheria; a doctor who tries to finesse with a swab when the trump card of antitoxin should be played, only too often, loses the trick.

Nasal diphtheria debilitates the child by a sub-acute toxic process and he is a danger to others rather than in immediate danger himself. A small dose of antitoxin by the intramuscular route speedily clears up the condition, the prognosis of which is very favourable.

Laryngeal diphtheria is sometimes primary but more usually secondary to a post-nasal focus in the infant or a faucial focus in the older child. The younger the child the more likely is the laryngeal form to occur and to result in a degree of obstruction necessitating *in addition* to antitoxin some form of intervention and to terminate in broncho-pneumonia caused by the downward spread of the specific and concomitant organisms. In private practice intervention must almost necessarily be tracheotomy with all its immediate dangers and the enhanced risk of subsequent broncho-pneumonia. In hospital practice prognosis in laryngeal diphtheria has become more favourable as the result of the intravenous injection of antitoxin, wherever possible, and the substitution, in suitable cases, of direct laryngoscopy and mechanical suction for intubation or tracheotomy. Not all cases are suitable or respond satisfactorily to this procedure. Tracheotomy may have to be performed in the end, but it is not infrequently obviated. Even in the mildest case of laryngeal diphtheria which appears to be responding to antitoxin, rest, and steam, the immediate prognosis should be very guarded. The sudden separation of membrane may cause the most urgent obstruction when all seems to be going well. Occasionally, too, there is a return of inspiratory stridor about the tenth day as part of the syndrome of serum sickness. Further, it has to be borne in mind that the child is still at risk from the late results of toxæmia especially, of course, if there was an associated extralaryngeal focus.

Faucial Diphtheria.—Given timely specific and skilled nursing treatment, the patient suffering from faucial diphtheria more often than not makes an uninterrupted recovery. But a minority of patients who have come under treatment late may, depending upon the initial severity of the infection and the time which this has gone unchecked, (1) die in the phase of initial toxæmia from acute myocarditis; (2) reach the stage of "convalescence" only to succumb after a succession of non-lethal forms of post-diphtheritic paralyses either to diaphragmatic paralysis or, more commonly, to myocarditis associated or not with heart-block; or (3) run the gauntlet of all these complications and at length recover completely. The clinical severity of faucial diphtheria is to be assessed by the extent and apparent age of the membrane and the concomitant local and general signs of toxæmia. The local signs are extensive and old membrane, fœtor, hyperæmia, and œdema of the fauces, and cervical adenitis and periadenitis. The general signs are prostration, pallor, and apathy or, in extreme cases, restlessness and delirium. The pulse is rapid, of low tension, and possibly irregular; pyrexia is slight or absent. Albuminuria is the rule. In the milder grades of the disease antitoxin by the intramuscular route and complete rest for some weeks suffices, but in the toxic case the intravenous injection of anything from 50,000 to 150,000 units is essential. The toxæmia of diphtheria results in profound disturbance of carbohydrate metabolism. Blood-sugar tolerance curves are of diabetic type. The greater the lag shown by the curves the worse the prognosis. In the toxic case prognosis, immediate and remote, is definitely improved by the exhibition, in addition to antitoxin, of glucose at first intravenously, and then, for the next ten days at least by mouth. The occurrence of post-diphtheritic paralysis of any type and however slight in degree is to be regarded as a danger signal—an indication of the fixation of toxin, the extent and gravity of which will only be fully revealed in the succeeding days. Palatal paralysis is usually first noted, and whatever the stage of the illness, absolute rest in a recumbent position without pillow must at once be resumed.

The two events to be feared are cardiac failure and diaphragmatic paralysis. The clinical onset of either is sudden and the prognosis of both very grave.

In hospital practice early warning of impending *cardiac trouble* is sometimes obtainable from serial electrocardiograms, but the cardinal clinical symptoms are *vomiting, epicardial pain,* and a subnormal temperature. The signs are those of cardiac dilatation associated in many cases with heart-block of varying grades and enlargement of the liver. Prompt resort or return to intravenous glucose therapy is essential and sometimes results in recovery in an apparently hopeless case. Adrenaline or ephedrine may be of value, and a very small dose of morphia (1/32 to 1/16 of a grain) by affording the child rest and relief from the distressing anginal pain occasionally helps to turn the scale. The ordinary cardiac drugs are of no value in this condition.

Diaphragmatic paralysis, which is not uncommonly associated with pharyngeal paralysis and gravely damaged heart muscle, may be of short duration, and the maintenance of a continuous supply of oxygen for 48 hours may tide the child over; but the prognosis is grave in the extreme. Evidence has been obtained in the wards of this hospital that the Drinker respirator, combined, if pharyngeal paralysis coexists, with periodical pharyngeal suction by means of an electric pump, is capable of saving some patients who otherwise, *from the observed duration of the condition,* must inevitably have died.

To hurry the convalescence of the diphtheria patient may be to ensure lasting myocardial weakness.

Even in the mild types of the disease a month of recumbency, followed by very gradual postural progress for the next fortnight, should be regarded as the minimum. A few cases of permanent heart-block have been recorded, and the rare post-diphtheritic hemiplegia results as a rule in recovery with permanent loss of function but, generally speaking, the post-diphtheritic lesions if they do not kill the patient at the time, in the end heal completely.

E. H. R. HARRIES, M.D., D.P.H.,
Medical Superintendent, North-Eastern Fever Hospital, London.

SPECIAL ARTICLES

EXAMINATION OF MILK PRODUCTS FOR TUBERCLE BACILLI AND BRUCELLA ABORTUS

BY E. J. PULLINGER, B.V.Sc. S. Africa,
M.R.C.V.S., Dip. Bact. (London)
RESEARCH INSTITUTE IN ANIMAL PATHOLOGY, ROYAL VETERINARY COLLEGE, LONDON

THE object of this investigation has been to inquire further into the incidence of tubercle bacilli and *Br. abortus* in dairy products, in view of the common occurrence of these two contaminants in raw bulk milk (Pullinger, 1934).

The following products have been examined.

1. *Cream.*—Fifty c.cm. samples were examined, each representing from 150 to 200 gallons of cream, prepared from milk produced in Cheshire, Wiltshire, or Somerset. The fat content of the cream tested was about 50 per cent. Cream from each supply was tested when raw and after flash pasteurisation at 180° F. (82·5° C.). The pasteurised samples represent the cream delivered for sale in London.

2. *Butter.*—Samples of factory, imported, and farmhouse butter were examined. Quarter-pound packets of salted and unsalted factory-made butter, prepared in Wiltshire, were picked at random from stock and were tested within 48 hours of manufacture. The samples were taken on different days. The cream used in the preparation of this butter had been flash pasteurised. In the case of imported butter sample plugs were taken from 1 cwt. consignments. Unfortunately, the country of origin of these samples is not known, nor could it be ascertained whether they were prepared from pasteurised cream. Farmhouse butter, prepared from raw cream at different farms, was received as 1 lb. samples and was examined within 48 hours of manufacture.

3. *Soft cheese.*—Packets of "Little Wilts" and "Bondon" cheese, as issued for sale, were examined, two packets being picked at random from stock each day. A few samples of each were examined immediately after manufacture. The majority were stored for two days, this being the minimum period allowed to elapse prior to sale. "Little Wilts" cheese is prepared from raw milk and "Bondon" from skimmed milk by a natural lactic fermentation process.

4. *Hard cheese.*—(*a*) Cheddar cheese, which is manufactured from raw or pasteurised milk, was examined when 7 days old. (*b*) Cheshire cheese, which is manufactured from raw milk, was examined when 7 days old; a second series was tested when 7, 21, and 49 days old; and a third series 3 months after manufacture, when ready for sale. (*c*) Stilton cheese, which is manufactured from raw milk, was tested when ready for sale, that is when more than 3 months old.

With the hard cheese, sampling was effected by taking two plugs from different portions of each cheese.

TECHNIQUE

The products were submitted to the biological test with guinea-pigs. Cream was inoculated through a wide-bore hypodermic needle, 1 c.cm. being injected intramuscularly into each thigh. Butter was melted at 40° C., and similar injections were made with syringes that had been warmed. Cheese was worked into a paste and then an emulsion, by grinding it in a sterile mortar with sterile distilled water. Saline proved unsuitable for the emulsification of cheese owing to the formation of a gummy precipitate. One c.cm. quantities of the emulsion were inoculated into each thigh through a wide-bore needle. Cream samples were each inoculated into a single guinea-pig; samples of the other products were each inoculated into 2 guinea-pigs. The technique of examining these animals was similar to that previously described.[1]

RESULTS

Results of the investigation are summarised in the Table.

1. *Cream.*—Out of 31 samples of raw cream, 16 contained tubercle bacilli and 11 *Br. abortus.* Of the samples which were contaminated, 8 contained both organisms, 8 tubercle bacilli alone, and 3 *Br. abortus* alone. Twelve samples were apparently free from both contaminants. Thirteen of the 31 samples came from

milk produced in Wiltshire or Somerset; of these, 2 contained tubercle bacilli and 2 *Br. abortus*. Out of 18 samples from Cheshire, 14 contained tubercle bacilli and 9 *Br. abortus*.

All 35 samples of pasteurised cream were free from these contaminants.

Out of 35 guinea-pigs inoculated with raw cream, 4 died from intercurrent infections, while none of the 35 inoculated with pasteurised cream died prematurely.

Examination of Milk Products for Tubercle Bacilli and Br. abortus

Product and class.	Remarks.	No. of samples.	Tubercle bacilli.		*Br. abortus.*		Both contaminants absent.

	49 ,, ,,	3	0	3	0	3	3
,,	3 months old	9	0	9	0	9	9
Stilton	,,	2	0	2	0	2	2

2. *Butter.*—Twenty samples of factory, 10 of farmhouse, and 9 of imported butter were examined. Of these 39 samples, none was contaminated. Out of 78 guinea-pigs inoculated with butter, 11 died prematurely.

3. *Soft cheese.*—Seventeen samples of "Little Wilts" cheese and an equal number of samples of Bondon cheese were examined. Three samples of "Little Wilts" were forwarded for examination immediately after preparation. None of these contained tubercle bacilli or *Br. abortus*, but two samples of "Little Wilts" contained saprophytic acid-fast organisms. A second series of 14 samples of each class was examined when the cheese was two days old and ready for sale. All these samples were free from the above contaminants. Out of 68 guinea-pigs, 17 died prematurely.

4. *Hard Cheese.*—(*a*) Neither tubercle bacilli nor *Br. abortus* were isolated from samples of 3 Cheddar cheeses examined 7 days after manufacture.

(*b*) Samples were taken from 6 Cheshire cheeses when they were 7 days old; of these, 1 contained tubercle bacilli and *Br. abortus*, 1 contained tubercle bacilli alone, and 4 were free from contamination. A second series of 3 cheeses was examined when they were 7, 21, and 49 days old. At 7 days, 2 cheeses contained both tubercle bacilli and *Br. abortus*. Neither of these contaminants, however, could be isolated after 21 or 49 days of storage. A third series of 9 cheeses was examined when more than 3 months old and ready for sale and of these none was contaminated.

(*c*) Two Stilton cheeses were examined at the time of sale, when more than 3 months old. Neither was contaminated.

Out of 55 guinea-pigs inoculated with suspensions of hard cheese, 11 died prematurely.

DISCUSSION

The results of the examination of raw cream coincided with the expectation formed from an examination of bulk milk from the two sources of supply. As previously reported,[1] 21 per cent. of herd bulk milk samples from Cheshire contained tubercle bacilli and 37 per cent. *Br. abortus*. In herd milks from Somerset the percentages were 2 and 19 respectively. Flash pasteurisation of cream in shallow layers at 180° F. (82·5° C.), if efficiently carried out, is shown to be destructive of pathogenic contaminants.

Since factory-made butter is prepared from pasteurised cream, the absence of contaminants was to be expected. As regards butter prepared from unpasteurised cream, only a limited number of samples could be examined. J. Smith (1934)[2] examined 51 samples of "locally prepared" butter and found tubercle bacilli in 5 instances. J. W. Edington (1934),[3] working with larger quantities of butter and using a somewhat elaborate technique, found that out of 40 samples of imported butter 1 contained tubercle bacilli. The imported butter examined by this worker was thought to have been prepared from pasteurised milk. The findings of Smith and of Edington considered in conjunction with the high incidence of pathogenic contaminants in raw cream, indicate that these organisms must be frequently present in butter made from unpasteurised cream. Efficient pasteurisation of cream is a safeguard against such contamination.

Although no pathogenic contaminants were found in soft cheese, the fact that saprophytic acid-fast organisms were isolated from very fresh cheese may suggest that tubercle bacilli also are able to survive the original manufacturing process. On the other hand, the fact that acid-fast organisms were not found in 28 samples of soft cheese which had been stored for 2 days suggests that autosterilisation occurs rapidly during the ripening period. A period of 2 days, however, would appear to be a very narrow margin of safety for the destruction of pathogens.

The fact that tubercle bacilli and *Br. abortus* were found in Cheshire cheese 7 days old, but not when 21 or more days old, indicates that, in the case of hard cheese also, autosterilisation takes place. Since such cheese must be allowed to mature for three months or more before it is sold, the margin of safety would appear to be adequate. The reason for autosterilisation of cheese is at present obscure. In the case of hard cheese it is known that the hydrogen-ion concentration changes during the course of ripening from pH 4·6 to 6·2, and it seems likely that the high hydrogen-ion concentration during the early stages of ripening may explain the destruction of tubercle bacilli.

No losses from intercurrent infection amongst guinea-pigs inoculated with pasteurised cream were experienced. This is similar to the very low mortality of 2·5 per cent. which followed the inoculation of 78 guinea-pigs with pasteurised milk.[1] The mortality following the inoculation of raw cream resembled that of 11·5 per cent. resulting from the inoculation of raw rail-tank milk. The inoculation of butter and cheese was followed by a high mortality of 15 to 25 per cent.

SUMMARY

1. The occurrence of tubercle bacilli and of *Br. abortus* in raw cream is noted.

2. Contaminants were not found in any of the samples of butter examined, but the majority of samples were prepared from pasteurised cream.

3. Tubercle bacilli and *Br. abortus* may be found in hard or soft cheese immediately after manufacture,

but auto-sterilisation occurs during the ripening period. In the case of soft cheese the ripening period is short, and the possible danger of tubercle bacilli surviving is correspondingly greater.

4. Efficient pasteurisation of milk or cream is an adequate precaution against the survival of tubercle bacilli and *Br. abortus*. Where the heating process does not interfere with subsequent manufacture of milk products such pasteurisation should be carried out.

5. The losses from intercurrent infections, amongst guinea-pigs inoculated with the milk products examined, are noted; and the mortalities are compared with those which follow the inoculation of milk.

I am indebted to the directors of United Dairies Limited for their interest and financial support, and to Mr. E. B. Anderson, M.Sc., for arranging for the supply of samples, and for providing information relating to products examined and details of manufacture.

THE MIDDLESEX HOSPITAL

As briefly announced last week, the new buildings of the Middlesex Hospital were opened on Wednesday, May 29th, by H.R.H. the Duke of York, when His Royal Highness was able to congratulate the governors of the institution on having raised the whole capital cost required. The Duke, who was accompanied by the Duchess, was met outside the main entrance by the chairman of the hospital, Prince Arthur of Connaught, and the terrace in the courtyard served as a platform for the speakers and guests of honour.

Prince Arthur of Connaught, in welcoming His Royal Highness, detailed some of the more important steps which had marked the progress of the hospital. He spoke of Sir John Bland-Sutton's Institute as one of the most valuable gifts ever made to medicine, valuable in itself and in its inspiration to others. This Institute was followed by the Courtauld Institute of Biochemistry, while Mr. Courtauld had also provided the science of medicine, in association with the Middlesex Hospital, with another new conception, the Clinical Research Unit where the professors of pathology, biochemistry, and physiology were directly in charge, and also in association with members of the clinical staff of the hospital. Of the developments in X ray and radiotherapy work, Prince Arthur said that the medical staff of the Middlesex were recognising the two different aspects presented—the therapeutic and the diagnostic—and named the benefactors whose great generosity was enabling both branches to develop. The radiotherapy department, the gift of Mr. E. W. Meyerstein, would, he said, shortly come into being, when the previous visits of inspection by the staff and selected experts to other scientific centres would assure to the hospital a first-rate department. The X ray diagnostic department, the gift of Mr. W. H. Collins, and already in operation, contained a plant unrivalled in other institutions. Prominent features in the work of the hospital which Prince Arthur mentioned, in illustration of its wide development, were the establishment of a complete unit to follow fracture cases from start to finish; and the construction of a model nurses' home, to which home Dr. Essex Wynter had added the perfect finishing touch by the presentation of his beautiful house, Bartholomew Manor, Newbury, as a home for retired nurses.

The Duke of York, in declaring the buildings open, recalled in particular the long association of the Middlesex Hospital in attempts to relieve cancer and to elucidate its problems.

"As President of the British Empire Cancer Campaign," he said, "I congratulate the Middlesex Hospital in playing a very important and distinguished part in the fight against a dread disease. I am happy to see with us to-day the Earl of Athlone, who was formerly chairman of this hospital, and was the first chairman of the council of the Campaign. The importance of early treatment of cancer has been urged again and again by yourselves and by your kindred research centres. This new Middlesex Hospital, thanks to its most generous supporters, has been enabled to embody in its scheme of reconstruction provision for the most modern treatment of all branches of this noble work. Cancer is an evil which must and will be crushed, and I would like to see a Cancer Research Centre such as yours established in every university teaching hospital, not only in this country, but throughout the Empire."

His Royal Highness dwelt on the value of close coöperation in a teaching hospital between the medical school and the medical, surgical, and research work. He recognised the administration of the school compelled long and arduous work on the part of those supervising its welfare, and congratulated all those who had contributed to the prestige of the school.

Of Prince Arthur of Connaught's work he said:

"I am sure I am expressing the wish of everyone here to-day in congratulating you on your success of your appeal to those generous supporters of our voluntary hospital system. This response from so many kind-hearted men and women has enabled this beautiful sanctuary to be raised by skilful workmen for the relief of suffering humanity. I recognise the fact that during the greater part of that time you have had to contend with national depression and financial difficulties. I feel convinced that just as you have succeeded in raising the huge capital sum for these buildings, so you will find the money that will enable you to make the best use of them."

His Royal Highness declared the hospital open.

Mr. W. Sampson Handley, senior surgeon of the hospital and chairman of the medical committee, said that they believed that research was the key to progress, and that the hospital had come to be recognised as a place where the medicine and surgery of the future were fashioned. Certain of the basic principles of the treatment of cancer were first worked out in the Barnato Laboratories, and of late years two possible routes to the problem of the causation of cancer had been supplied by the Bland-Sutton Institute. The complete success of their rebuilding fund might be partly interpreted as a public endorsement of their board's research policy and an acknowledgment of its success. In their preoccupation with research the interest of the individual patient remained dominant, and it was a daily pleasure to observe how they were treated by *nurses and servants* of the hospital.

Mr. A. E. Webb-Johnson, chairman of the Plans Committee of the hospital, read a letter announcing a subscription of £50,000 towards the new X ray therapy department from Mr. Meyerstein, and also announced that Mr. W. H. Collins had promised to give a like sum for the endowment of his department of X ray diagnosis. He added that when the history of the hospital came to be written it must be remembered that Prince Arthur had accepted the chairmanship with the responsibility of raising the enormous sum of money [illegible] ch had been obtained.

The [illegible] with the National Anthem, when their Royal Highnesses made a tour of the new buildings.

GENERAL MEDICAL COUNCIL

SUMMER SESSION, MAY 28TH–31ST, 1935

Cases referred by the Dental Board

The Case of Walter William Holmes, registered as of 261, Albert-road, Jarrow, Co. Durham, "Dentist 1921."

The Dental Board had investigated and found proved charges alleging that Mr. Holmes had induced another registered dentist to sign a dental letter stating that he had examined and intended to treat a patient who had, in fact, been examined and treated by Mr. Holmes, who had been disqualified for such work by the Department of Health for Scotland. There had been no complainant, and respondent had not attended or been represented. The Board recommended that Mr. Holmes's name be erased from the Dentists Register.

Mr. Harper, solicitor to the Dental Board, read a letter from respondent, who was not present, and testimonials. After deliberation in camera the President announced that the Registrar had been directed to erase Mr. Holmes's name from the Dentists Register.

The Case of Robert Marley, registered as of 22, St. Luke's-road, Pontnewynydd, Mon., "Dentist 1921."

The Dental Board had investigated a charge of allowing an unregistered person to practise in his name. There had been no complainant; respondent had attended without legal representatives. The Board recommended the erasure of Mr. Marley's name from the Register.

Mr. Marley did not attend and was not represented. A letter from him was read by Mr. F. P. Winterbotham, Mr. Harper's partner. After deliberation in camera the President announced that the name would be erased from the Dentists Register.

Penal Cases Adjourned from Previous Sessions

Adjourned from June 1st, 1934, the Case of George Francis Donaldson Perrott, registered as of 25, Bromefield, Stanmore, Middlesex, M.R.C.S. Eng. 1928, L.R.C.P. Lond. 1928, who had been summoned to appear before the Council on the following charge:—

> "That you were convicted of the following misdemeanours, viz.: (1) On April 13th, 1933, at the Staple Hill, Bristol, Police-court, of being in charge of a motor-car when under the influence of drink to such an extent as to be incapable of having proper control, and were fined £50 and £2 6*s.* costs and your licence suspended for five years. (2) On Nov. 17th, 1933, at the Marylebone Police-court, of being drunk and disorderly, and were fined 10*s.* 6*d.* or seven days' imprisonment."

That had been the third time Mr. Perrott had appeared, and he had been put on two years' probation, requiring testimonials at the end of one year.

Mr. Perrott did not attend the present session, and was not represented. Mr. Harper, the Council's solicitor, said that no further complaint had been received, and satisfactory testimonials had been sent. The President thought the Council might be satisfied with this intermediate report and note its reception.

Adjourned from Nov. 29th, 1933, and Nov. 28th, 1934, the Case of James Scott Webster, registered as of 31, Bank-road, Bootle, Liverpool, M.B., Ch.B. 1928, U.Edin., who had been summoned to appear before the Council on two convictions for offences against the Dangerous Drugs Act.

The Council had found the charges proved and had postponed judgment until November, 1934. Mr. Webster had been too ill to attend then, and the case had therefore been again postponed. Mr. Webster now attended, and the facts were laid before the Council by Mr. Winterbotham, who read five testimonials. After putting a number of questions to Mr. Webster, and after deliberation in camera, the President announced that the Council had not seen fit to direct the erasure of Mr. Webster's name.

Adjourned from Nov. 28th, 1933, May 29th, 1934, and Nov. 28th, 1934, the Case of Victor Cecil Tughan, registered as of 4, Stanton-court, Greenhill, Weymouth, M.R.C.S. Eng. 1925, L.R.C.P. Lond. 1925, who had appeared before the Council after convictions for being under the influence of drink while in charge of a car.

At the conclusion of the hearing on May 29th, 1934, the President had announced the decision of the Council as follows:—

> "Mr. Tughan: I have to announce that the convictions alleged against you in the notice of inquiry have been proved to the satisfaction of the Council. These convictions indicate habits which are discreditable, as you yourself admit, to the profession. In order to give you an opportunity of reconsidering your habits and your conduct, the Council have postponed judgment on these convictions until November next. Before that date you will be required to send to the Registrar of the Council, for their use, the names of certain professional and other persons of standing in your neighbourhood who may be willing on application to testify as to their knowledge of your habits and conduct in the interval."

At the conclusion of the hearing on Nov. 28th, 1934, the President had announced the decision of the Council as follows:—

> "Mr. Tughan: The Council have decided to postpone further consideration of this case until the May Session, 1935. They wish me to point out to you that you have not, apparently, fully appreciated the importance of furnishing testimony to your conduct from persons who are fully qualified to give it. For instance, you say you have been acting as locum tenens to a number of practitioners. Testimonials from practitioners who were in that close professional relationship to you, among others, would have been useful, and you will no doubt bear that in mind six months hence."

Mr. Tughan attended. Mr. Harper explained that Mr. Tughan had for six months been resident whole-time medical officer at a private home for paying mental patients, and had submitted testimonials from colleagues on the staff. After deliberation in camera the President announced that the Council had not seen fit to direct the erasure of the name of Victor Cecil Tughan.

Adjourned from June 1st, 1934, the Case of William Samuel Dixon, registered as of The Surgery, Fifth-street, Horden, Co. Durham, M.B., B.Ch. 1923, U.Dub., who had been summoned to appear before the Council on charges of canvassing which the Council had found proved. Judgment, however, had been postponed. The complainants had been The London and Counties Medical Protection Society, on behalf of three doctors.

Mr. Dixon attended, accompanied by Mr. O. Hempson, solicitor, on behalf of the Medical Defence Union.

Mr. Harper, for the Council, explained that the complainants did not appear now, and that two of the three doctors had no further complaint to make. Dr. A. McL. Wilson, however, had sent a letter from his solicitors proffering further charges against Mr. Dixon —not of canvassing, but of violation of medical etiquette. This letter had been received three days before, quite out of time by the Standing Orders. Mr. Harper read this letter, and a later one from Dr. Wilson himself. Mr. Hempson raised no objection and said he had, since hearing of the letter the day before, succeeded in bringing evidence on both the complaints, although they were, he said, utterly trivial and utterly malicious. The Council decided to proceed, and Dr. Wilson entered the witness-box and gave details of the complaints, stating that Mr. Dixon had enticed away two of his patients. Mr. Hempson cross-examined, and the legal assessor asked a number of questions as to Dr. Wilson's object in bringing these fresh complaints.

Mr. Hempson called Mr. Dixon, who gave his own account of the circumstances; one case had been a serious emergency, and he had given first aid only; the other patient had absolutely refused to see Dr. Wilson. He had communicated with Dr. Wilson in both cases. The mother of the first patient and the husband of the second were called and confirmed Mr. Dixon's evidence. Mr. Hempson briefly addressed the Council, urging that the complaints had arisen out of vindictiveness, and that the demeanour of complainant and witnesses spoke for themselves. He put in testimonials to Mr. Dixon's conduct since the Council's first inquiry.

The Council did not see fit to erase Mr. Dixon's name.

New Penal Cases

CONVICTIONS FOR DRUNKENNESS

The Case of Alexander Beck Cluckie, registered as of 25, Brock-street, Bath, M.B., Ch.B. 1908, U.Glasg., who had been summoned to appear before the Council on the following charge:—

> "That you were convicted at the Bath City Police-court of the following misdemeanours, viz.: (1) On June 26th, 1922, of being drunk while in charge of a motor-car, and were fined 40*s.* and £10 10*s.* costs (date of offence, June 3rd, 1922); (2) On Nov. 14th, 1934, of driving a motor-car without a driving licence, and were fined 5*s.* (date of offence, Nov. 3rd, 1934); and (3) On Jan. 15th, 1935, (*a*) of being under the influence of drink to such an extent as to be incapable of having proper control of a motor vehicle of which you were in charge, and were fined £20 and £2 2*s.* special costs and disqualified for holding a licence for five years (date of offence, Jan. 7th, 1935), (*b*) of driving a motor-car while under the influence of drink and were fined £25 and £3 3*s.* special costs and disqualified for holding a licence for one year (date of offence, Jan. 14th, 1935)."

Dr. Cluckie appeared, but was not accompanied by counsel. Mr. Winterbotham laid the facts before the Council, and read a letter from Dr. Cluckie's solicitors setting forth extenuating circumstances. Testimonials from professional colleagues were also read, and it was stated that Dr. Cluckie had become a total abstainer.

Dr. Cluckie said he had been suffering from insomnia and low blood pressure before the convictions; that he had never taken alcohol during consulting hours; that he had since been under treatment and was now in normal health. He was determined never to take alcohol again.

After deliberation in camera the President announced that the Council had decided to postpone judgment for a year, subject to the production of testimonials at that time.

The Case of William Graham, registered as of Bridge House, Manor-road, Tynemouth, M.B., B.S. 1923, U.Durh., who was summoned before the Council as a consequence of his conviction on Jan. 28th of this year before the Newcastle Police-court on a number of charges connected with the driving of a motor-car on Jan. 19th while under the influence of drink.

Mr. Graham appeared, accompanied by Mr. Hempson, on behalf of the Medical Defence Union. Mr. Harper, laying the facts before the Council, said that Mr. Graham had been before the Council a year ago with reference to a conviction of manslaughter at Newcastle, and had been discharged. On that occasion there had been no question of drink; he had fallen asleep while driving. Mr. Hempson, on the respondent's behalf, said that at the time of the manslaughter Mr. Graham had been seriously overworked, and in falling asleep at the wheel had not been guilty of any offence as a doctor. In the second instance he had been very unwell, suffering from chronic laryngitis and running a temperature. He had taken one whisky and soda as a restorative, and it had gone to his head. This was an isolated instance, and not the ordinary case of a man given to over-indulgence. Since that date Mr. Graham had abstained from alcohol altogether, and Mr. Hempson repeated an undertaking given by the respondent. Testimonials were read from a doctor, a vicar, and a solicitor.

After deliberation in camera the President announced that the Council had decided to postpone judgment for a year, subject to the production of testimonials on demand, and warned Mr. Graham to be very careful.

The Case of Samuel Patrick McGrath, registered as of 27, St. Julian's Farm-road, West Norwood, S.E. 27, M.B., B.Ch. 1924, N.U.Irel., who had been summoned to appear before the Council after conviction on two occasions for being under the influence of drink while in charge of a motor-car.

Mr. McGrath attended, accompanied by Mr. Hempson. Mr. Winterbotham set the facts before the Council. Mr. Hempson pointed out that, at the time of the first incident, Mr. McGrath had been through a very worrying time, having received bad news of some relatives when he was working very hard. In the second incident his car had run into an obstruction at the edge of the road, and the steering-wheel had broken and struck his face, breaking his nose. He had been bleeding severely and was only half-conscious when the police had arrived. His unsteadiness of speech was explained by the blow in the face; his unsteadiness of gait by the injury to his knees where they had struck the dashboard. His local colleagues had subscribed to pay his fine and costs, and had written to him expressing sympathy. Mr. Hempson read testimonials. The Council, after deliberation, found the facts proved, but postponed judgment until May, 1936, subject to the usual provisos.

The Case of Cecil John Rhodes Morrison, registered as of c/o National Bank of India, 26, Bishopsgate, E.C. 2, L.R.C.P. Edin., 1925; L.R.C.S. Edin., 1925; L.R.F.P.S. Glasg., 1925, who had been summoned to appear before the Council on the following charge:—

> "That you were convicted of the following misdemeanours, viz.: (1) At the Grays Petty Sessions, on April 13th, 1934, of being under the influence of drink and incapable of proper control of a motor-car of which you were in charge, and were fined £20 and 10*s.* 6*d.* expenses and your licence was suspended for twelve months; and (2) At the Lambeth Police-court on March 5th 1935, of being drunk and incapable, and were fined ten shillings."

Mr. Morrison appeared but was not accompanied by a legal adviser. Mr. Harper, opening the case to the Council, said that the respondent had been cautioned by the Council in 1927 after conviction for being under the influence of drink. The respondent read a letter addressed by himself to the Council. He said that he was now strictly teetotal, and asked the Council to give him another chance. The Council postponed judgment until May next, subject to the usual provisos, and the President reminded Mr. Morrison that control over events was largely in his own hands.

The Case of James Francis Patrick Devlin, registered as of Old Chapel House, Richmond-hill, Leeds, M.B., B.Ch. 1916, N.U. Irel., who has been summoned to appear before the Council on the following charge :—

> "That you were on Jan. 16th, 1935, at the Huddersfield County Borough Police-court, convicted of the following misdemeanour, namely, of being under the influence of drink to such an extent as to be incapable of having proper control of a motor-car of which you were in charge, and were fined £20 and £3 9*s*. costs or three months' imprisonment in default, and your licence was suspended and you were disqualified for holding a licence for twelve months."

Mr. Devlin attended, accompanied by Mr. O. Hempson, solicitor. Mr. Harper, for the Council, stated that Mr. Devlin had been before the Council in 1932 having been convicted for being drunk in the public highway, for which he had been fined 5*s*., and for drunkenness in charge of a motor-car. The President had on that occasion directed some severe remarks to respondent. Mr. Devlin's defence to the present charge at the police-court had been that he had been overworked in a severe outbreak of diphtheria, and had snatched a short holiday on Boxing Day ; he had met some Irish friends at a football match, and had had several drinks with them after missing his lunch.

Mr. Hempson, on behalf of the respondent, pointed out that he was a careful and abstemious man except on isolated occasions, and said that he undertook to abstain from alcohol in any form for the future.

After deliberation in camera, the President said that the Council would give Mr. Devlin one more opportunity of overcoming the tendencies which had caused him to be summoned before them, and would postpone their judgment for twelve months, subject to the usual provisos.

TWO MISSING MICROSCOPES

The Case of Oladipo Lahanmi, registered as of 2, Levenshulme-road, Gorton, Manchester, L.M.S.S.A. Lond., 1932, who had been summoned to appear before the Council on the following charge :—

> "That you were on Oct. 12th, 1934, convicted at the Liverpool City Police-court (*a*) Of feloniously stealing a 'Baker' microscope of the value of £10, the property of the Incorporated Liverpool School of Tropical Medicine, and were fined £5 or one month's imprisonment in default ; (*b*) Of feloniously stealing a 'Leitz' microscope of the value of £15, the property of the Incorporated Liverpool School of Tropical Medicine, and were fined £5 or one month's imprisonment in default, to run concurrently with the previous sentence."

The respondent attended but was not represented. Mr. Winterbotham, reading from the respondent's written statement to the Council, said that Mr. Lahanmi had borrowed first one microscope and then the other from the school just before he sat for his examination, to help him with his work. He had then found it impossible to return them without attracting the notice of the authorities. A friend whom he had asked to help him had finally informed the authorities of the irregularity. Mr. Lahanmi produced a number of warm testimonials to his character. The President, announcing the decision of the Council, said that the convictions indicated a weakness which was a very bad start in a professional life, but that the Council had taken into consideration the respondent's youth and the other circumstances, and had postponed judgment for twelve months, subject to the usual provisos.

FALSE PRETENCES

The Case of William Forbes-Leslie, registered as of Birkwood, Banchory, Kincardineshire, M.B., C.M. 1891, U.Aberd., who had been summoned to appear before the Council on the following charge :—

> "That you were convicted at the Central Criminal Court at its sessions commencing on Jan. 15th, 1935, of conspiring with other persons to obtain sums of money from Herbert Stewart Saunders and others by false pretences, and were sentenced to two years' imprisonment."

Respondent was not present, nor was he represented. Mr. Harper outlined the case and read letters from respondent asking for adjournment. Mr. Harper observed that the Common Serjeant, in sentencing respondent, had said he was the master mind in the conspiracy and a dangerous criminal.

After deliberation in camera the President announced that the Registrar had been directed to erase from the Register the name of William Forbes-Leslie.

A CONVICTION FOR MANSLAUGHTER

The Case of Samuel Ramsay Sibbald, registered as of Mariners'-parade, Canning-place, Liverpool, M.B., Ch.B. 1900, M.D. 1905, U.Edin., who had been summoned to appear before the Council on the following charge :—

> "That you were at the Liverpool Assizes, at its sessions commencing on Jan. 28th, 1935, convicted of manslaughter, and sentenced to five years' penal servitude."

Mr. Sibbald was not present or represented. Mr. Winterbotham put in the certificate of conviction and said the charge had originally been one of murder arising out of an illegal operation. The judge had said that he did not think the jury could have come to any other conclusion, and that he could conceive no worse case of the kind.

The Council directed the erasure of the respondent's name.

FALSE CERTIFICATION

The Case of Paul Verlannes, registered as of Stratford-house, Market-street, Ilkeston, Derbyshire. L.R.C.P. Edin. 1918, L.R.C.S. Edin. 1918, L.R.F.P.S. Glasg. 1918, who had been summoned to appear before the Council on the following charge :—

> "That, being a registered medical practitioner, (*a*) You as medical referee to the Royal London Mutual Insurance Society, Limited, signed a confidential medical report to the said Society dated Sept. 13th, 1932, certifying that you had personally examined one Leonard Charles Lidster, and recommended the directors to accept him as a first-class life, whereas you had never seen or examined the said Leonard Charles Lidster ; (*b*) You as medical referee to the Royal London Mutual Insurance Society, Limited, signed a confidential medical report to the said Society dated Jan. 12th, 1933, certifying that you had personally examined one Horace Steel, and recommended the directors to accept him as a first-class life, whereas you had never seen or examined the said Horace Steel ; (*c*) You as medical referee to the Royal London Mutual Insurance Society, Limited, signed a confidential medical report to the said Society dated July 12th, 1932, certifying that you had personally examined one John H. Atkin, and recommended the directors to accept him as a first-class life, whereas you had never seen or examined the said John H. Atkin ; (*d*) You as medical referee to the Royal London Mutual Insurance Society, Limited, signed a confidential medical report to the Society dated Sept. 13th, 1932, certifying that you had personally examined one Walter Davy Holmes and recommended the directors to accept him as a first-class life, whereas you had never seen or examined the said Walter Davy Holmes. And that in relation to the facts so

The President, in announcing the decision of the Council, said that the facts had been found proved and that they brought Dr. Crofton within the terms of the Warning Notice. The Council took a serious view of the offence, but postponed their judgment until May, 1937, subject to the usual provisos. He added that any method of treatment was open to any registered medical practitioner to use, but enthusiasm was no excuse for advertising.

The British Pharmacopœia

The PHARMACOPŒIA COMMITTEE reported that Sir Henry Dale had been appointed chairman for the ensuing year. The number of copies of B.P. 1932 sold to date has been 37, 631. Various subcommittees of the Pharmacopœia Commission are working on the Addendum, and conducting, in the laboratory over the G.M.C. offices, investigations for the descriptions of tests and assays and for the fixing of standards. A committee of experts has been formed to deal with vitamins and their preparations. The sections of the Pharmacopœia in which references to vitamins are made have been revised, and new monographs on products containing vitamins A, B_1, C, and D have been prepared, together with appendices describing the appropriate methods of assay. The subcommittee on serological and bacteriological products have completed their work, and have prepared descriptions of gas-gangrene antitoxin (œdematiens), gas-gangrene antitoxin (vibrion septique), staphylococcus antitoxin, antipneumococcus serum (Type I) and antipneumococcus serum (Type II), together with methods for their assay. For the vitamins and for the antitoxins and sera the international units and standard preparations have been adopted, and the requirements and tests have been brought into line with the decisions of the Permanent Commission on Biological Standardisation of the Health Organisation of the League of Nations. With the coöperation of the Rockefeller Foundation it has been possible to include tryparsamide in the Addendum. Recent discoveries on the active constituents of ergot have made it advisable for the Commission to review this drug. In 1930 the Commission received a request from the director of the Imperial Institute that the seeds of strophanthus emini, a product of Tanganyika Territory, might be considered for inclusion in the Pharmacopœia. Information regarding the chemistry, pharmacognosy, pharmacology, and clinical effects of the seeds has been collected and published.

Sir Henry Dale said that the Addendum was expected to be ready for publication next year.

VITAMINS IN THE PHARMACOPŒIA

Dr. H. G. Dain said that, having been concerned with the provision of drugs for insured persons, he had found considerable difficulty in drawing the line between foods and drugs. Since the products which contained vitamins should, in the ordinary way, be foods, the increase in the number of articles which appeared in the Pharmacopœia because of their vitamin content would make the distinction between foods and drugs more difficult. There was, of course, no reason why these substances should not be in the Pharmacopœia, but there was a question of policy—whether it was not a good thing to enable both the profession and the public to realise that vitamins should not be regarded as drugs. Though they might be necessary for the cure of certain conditions, they were necessary as foods. Some day the Government, under the advice of its then chief medical officer, would take steps to see that common articles of food should contain the vitamins that should properly belong to them if the health of the public were to be maintained. He asked Sir Henry Dale whether the food value of such constituents as were likely to be put into the Pharmacopœia were receiving the attention of the committee from the aspect of their food value.

Sir Henry Dale replied that Dr. Dain need have no apprehension. Everybody realised that a good deal of vitamin work and vitamin research lay on the borderline between therapeutics and nutrition. The changes now contemplated should make it clear that the aim of the Pharmacopœia was not to establish standards for substances which would properly be regarded as normal articles of diet and not as medicinal remedies. The present tendency, in fact, was in the other direction. Vitamins C and D, for which new monographs were to be produced, had both, between the issue of the 1932 Pharmacopœia and the preparation of the Addendum, been isolated in chemically pure form. Apart from the need for them in a normal diet, at the present stage of social development numerous cases would come under treatment by medical practitioners requiring the administration of vitamins in the most concentrated and immediately active form that could be obtained. The duty of the Pharmacopœia was to see that any potent remedy of this kind which the profession required should, apart from any question of general policy, be properly standardised, and this was the aim of the monographs in the Addendum.

Other Committee Business

The Council accepted the recommendation by the EDUCATION COMMITTEE that this committee should reconsider the regulations in regard to the registration of medical and dental students with a view to the removal of discrepancies in practice, especially those due to the revision of the curriculum.

The EXAMINATION COMMITTEE stated that the vacancies occurring in the medical services of the Crown continued to be filled by selection and that no competitive examinations had been held during 1934. It reported on the visitation of examinations held by various licensing bodies, and appended to its report some interesting tables showing the results of examinations during last year, with the numbers of students who had passed and failed.

MEDICINE AND THE LAW

Claim against Hospital and Surgeon

IN an action, heard before Mr. Justice Swift and a special jury last week, Mr. J. W. James sued the chairman and 29 members of the committee of the Royal Victoria Hospital, Folkestone, for damages for a surgical drainage-tube left in his body after an operation. He also sued Mr. W. W. Linington, the surgeon who had operated upon him. Mr. James had consulted Mr. Linington in March, 1928, and was sent to the hospital next day, where he was found to be suffering from pneumonia and pleurisy. On April 3rd Mr. Linington removed part of his rib and a drainage-tube was inserted. On May 17th the patient left the hospital, but continued to attend daily for the changing and sterilising of the tube till August, 1928, when he was discharged. Under medical advice he went abroad to Florida, where he enjoyed good health. Returning to England in May, 1929, he afterwards felt ill and eventually went to the Brompton Hospital, where he underwent an operation on March 8th, 1933. In the old wound was found a half-perished rubber drainage-tube, 4½ inches long. This was extracted and the patient's health has been good ever since. Mr. James said that nobody at the Brompton Hospital told him what had been found, but he discovered the information by reading his case sheet, which had been inadvertently left on his bed. In support of his claim, Mr. James said he remembered an occasion after the first operation, when a nurse appeared to remove from his wound a shorter piece of tube than had been inserted. It was apparently suggested that the drainage-tube was 6 inches long, and that on this occasion a piece 1½ inches long was removed, leaving 4½ inches still in the body. Mr. James was asked why he did not make any comment; he replied that he would have got no answer from the nurse, because she was acting in the ordinary routine of the hospital. On the other side there was evidence that it was almost impossible to break surgical tubing, that it would take years to perish, and that there was nothing in the wound on which the tube could catch.

At the close of the plaintiff's case it was submitted that the committee of the Folkestone Hospital had no case to answer. Although Mr. James had paid £15, it was a voluntary donation, and there was no contract between him and the hospital. His action against the hospital was brought upon an allegation of negligence. The managers and trustees of the hospital contended that their only duty was to use due care and skill in choosing the medical staff, and to see that patients were treated by experienced doctors and nurses; the relationship of master and servant did not exist between the governors of a public hospital and the surgeons who gave their services to the hospital; during an operation the nurses were not the servants of the governors because, for the time being, they took their orders from the operating surgeon only. The judge accepted these arguments and dismissed the action as against the committee of the hospital.

There remained the claim against the operating surgeon, whose defence was conducted by the Medical Defence Union. There was only one occasion when he had put in a tube (in April, 1928); the nurses must have dressed the wound and inserted tubes dozens of times. Somebody had undoubtedly been negligent, but Mr. James had to prove beyond reasonable doubt that the cause of his injury was some negligent act by Mr. Linington. This he failed to do. The jury and the judge expressed sympathy for the plaintiff, but a verdict was given for the defendant surgeon with costs.

Introductions in Medical Partnership

In articles of medical partnership there is usually a covenant that a retiring partner shall not attempt to practise within a certain radius of the partnership premises for a named period of years without the consent of the other party. A recent case in the Chancery Court in Manchester arose out of the soliciting of former patients of the partnership by the retiring partner. Dr. A paid Dr. B £1400 for two-fifths of his practice in 1929. He bought the other three-fifths for £1556 in 1934, in which year Dr. B retired. Their articles of partnership contained the usual covenant preventing Dr. B from attending former patients within a five-mile radius. It was nevertheless agreed that, notwithstanding the covenant, Dr. B might attend not more than 12 former patients within the radius if they specially requested his personal treatment and said they were not prepared to be attended by Dr. A or his partner. Such attendances by Dr. B were to be on behalf of Dr. A's practice, and Dr. A was to receive the fees, subject to a deduction of one-third in favour of Dr. B. Some weeks before Dr. B actually retired he sent out a circular stating that, after the date of his retirement, he would be at liberty to attend any of his former patients who did not desire the services of Dr. A or his partner. Dr. A thereupon asked the court for an injunction and damages. Dr. B's conduct was a breach of the agreement, and it infringed the general law of partnership. A retiring partner who sells his interest in a medical practice is in the position of a business man who sells the goodwill of his business. The law forbids a man who sells the goodwill of his business to solicit the old customers afterwards; the seller must not "derogate from his own grant" and injure the goodwill he has sold. In the case at Manchester the court held that Dr. B had broken this principle by his circulars. An injunction was granted against Dr. B with an inquiry as to damages. In medical partnership disputes there is often a complaint that the newcomer has not been properly introduced to the patients of the partnership. This point also was raised by Dr. A in the Manchester case. The judge said it was an ordinary custom that the purchaser of a share in a medical practice should be taken round and introduced to patients. Dr. B had undertaken to introduce Dr. A and had failed to do so. The court directed an inquiry to ascertain what damages, if any, had arisen from this breach of agreement. Dr. B was ordered to pay the costs of the action, the costs of the inquiries being reserved.

The Name of a Hospital

A special meeting of the court of governors of the Anti-Vivisection Hospital at Battersea passed last week, by a majority of 42 votes to 3, three resolutions for deleting all references to antivivisection in the memorandum of association of the hospital, and for changing the official name to the Battersea General Hospital, the title by which it has already been unofficially known. Lord Ernest Hamilton, the chairman, told the meeting that, if the resolutions were not passed, the hospital might as well close its doors the next day. He attributed the heavy indebtedness of the hospital to the "ceaseless hostility" and "fanatical bigotry" of the administrators of King Edward's Hospital Fund for London, who had refused all help. He reported his negotiations with them, and announced that the changes would bring a prospect of financial assistance, though the administrators of the Fund had intimated that, even if the name of the hospital were changed, they could not guarantee support. The passing of the resolutions indeed does not conclude the matter, since the hospital governors are trustees of a fund to be used for antivivisection purposes and an application to the law courts will be necessary. Before the meeting Lord Ernest is reported to have informed an interviewer that the "antivivisection" part of the hospital's name was "a meaningless term pinned to it many years ago and a great handicap." This mild description is not easily reconciled with the provocative policy for which Battersea has stood in the past. If, however, the hospital can now surmount its financial and legal difficulties, there need be no obstacle to its fruitful coöperation with other hospitals in the service of the public.

Treasure Trove

Judicial humour has its own perils, and some playful remarks by Lord Hewart about treasure trove have drawn a correction from the official head of the British Museum. The Lord Chief Justice, who by his office is himself chief coroner of England, was invited to open the reconstructed coroner's court for the City of London in Golden-lane on May 28th. Having explained that coroners are not exclusively concerned with inquiries into death, he went on to allude to their other surviving functions. In an allusion to treasure trove, he remarked, "If one of you has recently found good gold buried in the municipal park of your own particular domicile, I advise you that in this place it is not wise to divulge the discovery." Sir George Hill wrote to the *Times* from the British Museum to say that it would be a pity if this not very serious remark were to confirm the public in the mistaken notion that, if anybody finds a treasure, it will be taken by the police and the finder will get nothing. "It is to be feared that this delusion is shared even by coroners. The truth is that the honest finder who reports his find to the police either receives from the Crown the complete market value of his find, without deduction, or has his find returned to him." Sir George's statement does not quite tally with the notice sent by the Home Office to chief constables in 1925 when the Treasury reconsidered the arrangements for disposal of articles of treasure trove. It was then stated that if coins or other objects were required for the national museums, the finders would be paid the full antiquarian value, less a deduction of 20 per cent. But, whether or no there is a deduction, it is certainly important that treasure trove should be reported to the proper authorities and not concealed. Treasure trove, as coroners are aware, must be something intentionally hidden and not something lost or abandoned. A year ago an inquest was held on a guinea dated 1745 found on land adjoining Newbury racecourse. The jury held that this was not treasure trove, but the mere discovery of lost property. The coroner, in handing the coin back to the police, said he thought the finder was entitled to it.

SCOTLAND

(FROM OUR OWN CORRESPONDENTS)

THE HOSPITAL AS A LINK IN THE CHAIN

If hospitals tend to get patients too late they also tend to discharge them too soon. This is an opinion freely expressed, which Dr. Brownlie, chief medical officer of the Department of Health for Scotland, has discussed in a suggestive paper communicated, in absentia, to the International Congress of Hospitals held at Rome last month. This paper was entitled The Hospital as a Link of a Systematic Public Health Chain, and includes an analysis of the case records of patients discharged "from the wards of one of the best of our voluntary hospitals," which showed that only 14 per cent. were classified by the hospital staff as "cured" as against 56 per cent. "relieved." Many of these patients had been ill for months or years prior to admission to hospital, and the condition of many of them a few months after discharge was "as bad as it ever was." Is this true generally of the medical cases discharged from the general hospitals of Great Britain? Dr. Brownlie in his paper implied that it is, and he makes some interesting constructive proposals. These proposals for a more effective service throw into relief the position of the hospital as a link in the chain, and not the last link; and he attempts precision by advocating several specific measures to prevent what he calls "the stultification of the work of the hospitals." He gives the auxiliary hospital and the convalescent home their due place; but he lays most emphasis on the development of the out-patient department as the vital centre of a hospital's activity rather than a mere filter for determining suitability for admission to its wards. This is a good conception—not new, of course, but given here a new emphasis. He regards the out-patient department as the natural locus for the diagnostic centre whose establishment has been urged by the British Medical Association and other bodies; it is the natural centre also of follow-up activities. Dr. Brownlie points out that "the scientific investigation of the hospital may have determined for the patient a new scheme of essential values suited to his particular requirements—an appropriate dietary, a definition of permissible physical activity or an insulin dosage . . . but unless steps are taken to ensure that the outside practitioner is thoroughly conversant with the hospital findings and willing to continue to give his patients intensive supervision along the prescribed lines, subsequent relapse is almost inevitable."

The position is met at some hospital centres by an organised system of communication between the hospital staffs and the practitioner and by the almoner activities of the hospital. These activities are now to be extended to all the London County Council hospitals "for the purpose not only of considering the question of contributions by patients and relatives towards the cost of treatment, but also to act as social officers to give advice to patients, and to see not only that they get well but keep well." The almoners would not claim, however, that they can take the place of the practitioner as the essential link between patient and hospital; they supplement the practitioner's work; and the development of the almoner service in no way diminishes the need for closer coöperation between practitioner and hospital. The case for the out-patient department as the centre of coöperation remains. Dr. Brownlie speaks as a health administrator; he speaks therefore of an organisation in which, theoretically, clinics, dispensaries, auxiliary institutions and outdoor medical services (not to mention housing, public assistance, and other social services) function along with the hospitals in an integrated health service. The problem, therefore, of using the municipal general hospital as "a link of a systematic public health chain" is comparatively easy to solve. But what of the voluntary general hospital? It is, in most areas, an isolated unit. Can it continue in isolation and at the same time meet fully the need not only for comprehensive aids to diagnosis but also for active after-care of patients? Dr. Brownlie does not explicitly raise this issue; but it is the immediately practical one, since the voluntary hospitals still are and will long remain, the main centres of hospital treatment in Great Britain. This conception of the hospital as a link in the chain of preventive and constructive medicine is likely to do more to speed up coördination of voluntary and municipal hospital services than the mere adjustments of numbers of beds and the like have hitherto achieved.

DUKE OF KENT IN GLASGOW

During the visit of the Duke and Duchess of Kent to Glasgow last week, His Royal Highness opened new buildings at the Victoria Infirmary, which included a home to accommodate 145 nurses, and a wing for fee-paying patients. The cost of the buildings has been £80,000, and the total number of beds in the infirmary is now 477. The Duke also laid the foundation-stone of the Royal Infirmary auxiliary hospital and convalescent home at Canniesburn. The new building is to consist of three blocks connected together. The convalescent block will have accommodation for 80 patients, the west block is to be for paying patients and will contain 44 beds, while the central block is to house the administrative department and the kitchen and dining-room for nurses.

EDINBURGH MUNICIPAL HOSPITALS

A further step in the development of the Edinburgh municipal hospitals is the recommendation of the public health committee to proceed with the reconstruction scheme at the Western General Hospital. This hospital was erected in 1868 as a poor-house, and instead of attempting to reconstruct the existing buildings, it is proposed to build a new surgical unit seven stories in height, with 26 beds on each floor. A medical unit is also to be built, which will contain 182 beds. In addition to these improvements there will be a new X ray department and a new nurses' home. The total cost of the proposed extensions will be £120,000.

POLICE MEDICAL OFFICERS

The Glasgow corporation have been discussing the proposed appointment of two full-time medical officers to be attached to the police force. The Secretary of State for Scotland, after consultation with the Lord Advocate, has given his opinion that the time has now come when the whole of the medical and casualty surgical work in connexion with the police force should be performed by whole-time medical men employed by the police authority. In his view it is of the utmost importance in the interests of the rapid detection and suppression of crime, that police officers and police doctors should work in alliance immediately a crime has been discovered. For this purpose the service of whole-time medical jurists, who would be available at any hour of the day or night, is essential.

UNITED STATES OF AMERICA

(FROM AN OCCASIONAL CORRESPONDENT)

THE BASIC SCIENCE LAW

Sir Henry Brackenbury knows the medical problems in this country as well as he does those in his own. His distinction between the British and American systems of dealing with cultists as reported in your columns (THE LANCET, April 6th, p. 832) is good evidence of this. Those who have had experience of the American system of regulating the irregular practitioners will surely envy the Englishmen their single standard of qualification. The Basic Science Law, recently enacted in nine States, is the American method of recovering that single standard. The basic sciences as defined in the model Act are: anatomy, physiology, chemistry, bacteriology, and pathology. However, not all of the States that have adopted the law have retained this definition of basic sciences. Connecticut has hygiene and diagnosis in place of bacteriology and chemistry; Nebraska has added hygiene to the original list of five; Washington substituted hygiene for bacteriology; and Wisconsin dropped both chemistry and bacteriology and added diagnosis. The law limits membership of the examining board to members of the faculties of approved universities and colleges. This meets as far as it is possible to do so the inevitable accusation that the medical profession will exert prejudice in the examinations against members of the cults. The Act does not apply to dentists, pharmacists, nurses, optometrists, and chiropodists practising within the limits of their respective callings. B. J. Palmer, the father of chiropractic, has looked with envy on this list of exemptions. "You cannot defeat the ends of science," he has said. "The basic science bills are the buckshot which we deserve for trespassing. When chiropractors preach and practice and try to become physicians, then it is justifiable for the medical men to educate the chiropractor."

The ultimate success of the basic science laws depends upon education of the public to demand a minimum standard of preparation from all who are licensed to take into their hands the issues of life and death. It will obviously be years before the damage done to public welfare, through letting down the bars to quite uneducated healers with all kinds of fancy names, is repaired. Even now cultists are claiming and often obtaining the right to be employed under the provisions of federal emergency medical relief. But in the end the adoption of the Basic Science Law may recover for us something of the standard of medical practice which Britain enjoys.

PARIS

(FROM OUR OWN CORRESPONDENT)

THE SPENDING OF SICKNESS INSURANCE FUNDS

INSURED workers in France have for some years contributed substantial sums to the organisations which correspond to the English friendly societies, and now the very size of these sums is a source of national embarrassment. There seems inevitably to be an element of demoralisation in the large fortune to which there are many claimants, and a mighty tussle is in prospect over the disposal of the funds in question. Monsieur Queuille, the minister of public health, has recently taken the initiative in drafting a law providing for the coördination of schemes for spending the money on buildings and other works devoted to public health. His draft is now being considered by two other State departments, those of labour and finance, and when a[illegible]ment has been reached among them, it will be [illegible]mitted as a Bill to the Chamber of Deputies. [illegible] is already a network throughout the coun[illegible] public health centres concerned with tuber[illegible] venereal disease, cancer, and maternity an[illegible] welfare, and one of the most important ste[illegible] to [illegible] taken in the near future is to bring thes[illegible] centr[illegible] into the general public health scheme with[illegible]out over[illegible]lapping or friction. As in all other countries [illegible] which compulsory health insurance has been introduced, the interested parties in France are [illegible] forming well-defined groups for the defence of their particular interests. First there are the insured workers and the societies and officials representing them. Then there are the general medical practitioners who have hitherto enjoyed much independence, and who now find one function after another being removed from their hands. There is also the young but rapidly growing generation of doctors who se[illegible]e in the beginning of a State medical service openings which are not without attraction. Lastly, there are the highly placed State servants who must coördinate the whole and hold the balance as fairly as possible between the other parties. There is talk of some 975 schemes in the ministry of public health for the spending of insurance funds which have recently been valued at more than 1300 million francs. It is going to be no easy task to convert this stupendous sum into hospitals, sanatoriums, preventoriums, laboratories, dispensaries, and playgrounds for children.

low incidence of diphtheria, which he attributes to the success of the immunisation campaign. Toxoid antitoxin floccules are being used so that reactions are avoided, and the preliminary Schick test has been abandoned because experience has shown that, in this agricultural area, 80 per cent. of the children are Schick-positive. This may be all the more reason for doing a late posterior Schick test, at least on a fairly large sample of the immunised, since it has been found that communities less exposed to natural, if latent, immunisation are rather more difficult to immunise artificially. Acceptances are satisfactory. Seven schools were dealt with during the year. In three of them over 90 per cent. of the parents consented, 80 per cent. in another, between 70 and 80 per cent. in two, and 54 per cent. in the remaining one. During the past two years 2000 persons have been immunised. In Holland immunisation appears to be regarded legally as a function of the sanitary authority, Dr. Booth acting for them at their expense. The legal position is a little obscure. Under Section 80 of the Education Act, 1921, a local education authority—i.e., a county council, except in the case of the larger urban areas—may do anything for the health and physical welfare of the school-children to which the Minister of Health consents. The position of maternity and child welfare authorities (which may be county councils or county district councils) is similar under Section 1 of the Maternity and Child Welfare Act, 1918, and the Minister has given a general consent to extensions of schemes such as immunisation at centres would involve. Apart from these provisions, which cover most of the population requiring this form of attention, it would appear that the county district councils (i.e., sanitary authorities) can only undertake immunisation in virtue of Section 133 of the Public Health Act, 1875, which requires an explicit sanction from the Minister of Health.

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDED MAY 25TH, 1935

Notifications.—The following cases of infectious disease were notified during the week: Small-pox, 0; scarlet fever, 2142; diphtheria, 1018; enteric fever, 23; acute pneumonia (primary or influenzal), 945; puerperal fever, 46; puerperal pyrexia, 108; cerebro-spinal fever, 20; acute poliomyelitis, 3; encephalitis lethargica, 10; continued fever, 1 (Rhondda); dysentery, 22; ophthalmia neonatorum, 107. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the London County Council on May 31st was 3061, which included: Scarlet fever, 913; diphtheria, 1209; measles, 31; whooping-cough, 389; puerperal fever, 27 mothers (plus 12 babies); encephalitis lethargica, 268; poliomyelitis, 3. At St. Margaret's Hospital there were 17 babies (plus 8 mothers) with ophthalmia neonatorum.

Deaths.—In 121 great towns, including London, there was no death from small-pox, 2 (1) from enteric fever, 22 (1) from measles, 6 (0) from scarlet fever, 22 (1) from whooping-cough, 48 (9) from diphtheria, 49 (11) from diarrhœa and enteritis under two years, and 70 (8) from influenza. The figures in parentheses are those for London itself.

The only death from enteric fever outside London occurred at Edmonton. Five deaths from measles were reported from Birmingham, 4 from Liverpool, and 3 from Walsall. No great town reported more than 2 deaths from whooping-cough. Liverpool had 3 fatal cases of diphtheria, West Ham, Manchester, Preston, Sheffield, Birmingham, and Burton-on-Trent each 2. Of the deaths attributed to influenza 9 occurred at Manchester, 5 at Bradford, and 4 at Leeds.

The number of stillbirths notified during the week was 274 (corresponding to a rate of 38 per 1000 total births), including 43 in London.

THE SERVICES

ROYAL NAVAL MEDICAL SERVICE

Surg. Rear-Admiral H. R. H. Denny, C.B., has been appointed Hon. Surgeon to the King, from May 8th, in the vacancy caused by the retirement of Surg. Rear-Admiral W. W. Keir, C.M.G.

Surg. Comdr. J. H. B. Crosbie to *Drake* for R.N.B.

Surg. Lt.-Comdr. C. Keating to *Victory* for R.N.B., and to *St. Angelo* for R.N. Hospl., Malta.

Surg. Lt.-Comdrs. G. Rorison to *Faulknor*, on commg., and J. M. Sloane to *Victory* for R.N.B.

Surg. Lts. (Short Service) S. K. Foster, J. W. Oliver, H. de B. Kempthorne, F. M. Duthie, and T. McCarthy, transferred to permanent list, with original seny.

Surg. Lt. F. M. Duthie to *Victory* for R.N.B.

ROYAL NAVAL VOLUNTEER RESERVE

Surg. Lt. J. E. L. Morris and Proby. Surg. Lt. J. L. Dunlop to *Tiverton*.

Proby. Surg. Lt. (D.) J. W. W. James, L.D.S.U., to be Surg. Lt.

ROYAL ARMY MEDICAL CORPS

Short Serv. Commissions.—G. S. Musgrove to be Lt. (on prob.), Lt. (on. prob.) G. C. Dansey-Browning is secd, under the provisions of Art. 213, Royal Warrant for Pay and Promotion, 1931.

Temp. Commissions.—Maj. F. C. Doble relinquishes his commn., and retains the rank of Maj.

REGULAR ARMY RESERVE OF OFFICERS

The undermentioned having attained the age limit of liability to recall, cease to belong to the Res. of Off.:—Col. W. R. P. Goodwin, D.S.O. (late R.A.M.C.), Maj. G. H. Rees.

TERRITORIAL ARMY

Capt. G. T. Symons to be Maj.

TERRITORIAL ARMY RESERVE OF OFFICERS

Lt.-Col. W. D. Sturrock, D.S.O., having attained the age limit retires and retains his rank, with permission to wear the prescribed uniform.

ROYAL AIR FORCE

*The undermentioned are granted short service com*missions as Flying Officers on probation for three years on the active list, with effect from May 7th, 1935:—R. C. H. Tripp, P. A. Cooper, L. E. A. Dearberg, H. L. Willcox, and A. R. C. Young.

Flight Lt. P. D. Barling is promoted to the rank of Squadron Leader.

Wing Comdr. A. J. Brown, D.S.O., *is placed on* the retired list.

Dental Branch.—Flying Offr. R. H. Marthews, L.D.S., is promoted to the rank of Flight Lt.

Flying Offr. A. W. Smith to R.A.F. General Hospital, *Hinaidi, Iraq.*

INDIAN MEDICAL SERVICE

Lt.-Col. W. J. Simpson retires.

Capt. S. S. Ahluwalia resigns his temp. commn.

Indian Medical Department.—The undermentioned retire: Maj. (Sen. Asst. Surg.) F. W. Holmes and Maj. (Sen. Asst. Surg.) R. H. G. Thompson.

The list of earthquake casualties reported from Quetta includes the names of Lt.-Col. B. C. Ashton, I.M.S., and Major J. G. Bird, I.M.S., amongst the injured.

BRIGHTON AND HOVE DENTAL HOSPITAL.—Owing to continued lack of support the work at this hospital has had to be curtailed. The move to the present building in Buckingham-road, Brighton, from the inadequate accommodation in Queen's-road, has been fully justified; but the mortgage remains an anxiety and a burden. Until it is paid off it will be impossible to buy an X ray apparatus. It was stated at the annual meeting of the governors that the income from subscriptions last year was only £37. A special appeal is to be made in the autumn. The institution was established in 1887 and will observe its jubilee in two years' time.

CORRESPONDENCE

LONDON HOUSE

To the Editor of THE LANCET

SIR,—We are anxious to direct the attention of the medical profession to a letter, signed by General Smuts, Mr. Bruce, Sir Robert Borden, Sir James Parr, and Lord Lugard, and a leading article in the *Times* of May 27th.

In this letter an appeal is made to the public to support financially a scheme for the completion and endowment of London House, an institution which has already proved invaluable to a large number of post-graduate medical students from overseas and which is destined to play a very important part in the educational life of the Empire.

London House, situated in Mecklenburgh-square and opened in 1931, owes its origin largely to the enthusiasm and hard work of the late Mr. Frederick C. Goodenough, whose ambition it was to establish a home for students from all parts of the Empire with amenities and facilities for the completion of their education similar to those afforded by the colleges of our more ancient universities.

The Carnegie Corporation, already generous donors, have promised a further sum of £20,000, provided that £30,000 can be raised from other sources, and it is calculated that the total of at least £50,000 will be necessary for further building and endowment purposes.

This year is remarkable for efforts to make London a worthy centre of Imperial Medicine, and to bring members of our profession all over the world into closer relationship. The opening of the Postgraduate School at Hammersmith by Their Majesties the King and Queen is to be followed by a meeting of the British Medical Association in Melbourne, which means that several hundred practitioners will be traversing and visiting several of the Dominions. We are afforded, therefore, the opportunity for making the advantages and needs of London House well known all over the Empire and for stimulating the profession and its friends, overseas as well as at home, to unite in giving a great project all the support and encouragement it deserves.

Contributions may be sent to the Hon. Treasurer of London House, 54, Lombard-street, London, E.C. 3.

We are, Sir, yours faithfully,

DAWSON OF PENN,
HOLBURT WARING,
MOYNIHAN,
HORDER,
FREDERICK MENZIES,
W. LANGDON-BROWN,
E. FARQUHAR BUZZARD.

May 31st.

LEAGUE OF NATIONS REPORT ON THE TREATMENT OF SYPHILIS

To the Editor of THE LANCET

SIR,—Since the publication of the *Quarterly Bulletin* for March, 1935, of the Health Organisation of the League of Nations, which contains the report of an expert committee summarised in your issue of May 18th (p. 1170), I have repeatedly been asked why it is that among the 29 British clinics which submitted their records the name of no Manchester or Salford treatment centre appears. For Manchester I cannot speak; but so far as Salford is concerned the reason is that no invitation was issued to it.

This explanation seems to be necessary in view of the statement made in the report that "In each of these countries the dermatological and venereal disease clinics were appealed to for their support, and a large majority readily responded." It might be thought, on looking at the table of British clinics, that the Salford municipal clinic—one of the largest in the country—refused to take part in the investigation. I want to make it perfectly clear that not only was this clinic not asked to submit its records, but it did *not receive any official intimation* that such an inquiry was in progress.

The omission of the Salford municipal clinic is the more remarkable because it and one other are the only treatment centres in Great Britain where the alternating and continuous method of therapy is in operation. I am, Sir, yours faithfully,

Municipal Clinic, Salford, May 30th. E. T. BURKE.

STIMULANTS OF METABOLISM

To the Editor of THE LANCET

SIR,—We fear that Dr. Newcomb has misinterpreted our letter in THE LANCET of May 25th. Sir William Willcox conveyed the impression that given in recognised therapeutic doses nitrophenols cause damage to liver and kidney. We emphasised that in therapeutic doses it was impossible to obtain any evidence of damage to liver or kidney. Dr. Newcomb, however, was referring to a case in which there was a gross overdosage. We feel that it is only fair to stress the difference between his observations and our own results obtained from a study of persons and animals to whom normal doses of the substance were administered. We wish to make it clear that we were concerned solely with the alleged toxicity of these compounds and made no reference to the relative merits of various methods of treatment for obesity. The question of the state of mind of one of us (E. C. D.) on this point does not therefore arise.

We are, Sir, yours faithfully,

E. C. DODDS,
J. D. ROBERTSON.

Courtauld Institute of Biochemistry, Middlesex Hospital, June 3rd.

ADMINISTRATION OF CARBON TETRACHLORIDE FOR HOOKWORM

To the Editor of THE LANCET

SIR,—In your last issue Dr. A. S. Tuxford suggests that to give carbon tetrachloride shaken up in castor oil makes for safety. G. Giglioli felt that the same result was produced by shaking it up in water (Trans. Roy. Soc. Trop. Med. and Hyg., 1924, xviii., 111). Both opinions are formed on uncontrolled experiments of insufficient extent, and accordingly have no stable foundation. As to efficacy both series of observations were made by treating men in herd fashion, it being unknown whether, at the time of treatment, they were even infected; accordingly the efficacy of the treatment used by Dr. Tuxford is unknown. As to animal experiment, the only evidence in any way apposite which I have traced is by Maurice C. Hall (Jour. Agric. Research, 1921, xxi., 157), who recovered no hookworms after treating a dog with 0·3 c.cm. of carbon tetrachloride per kg. body-weight, followed immediately by castor oil; the sufficiently meagre evidence is against the anthelmintic value of the suggested method of administration, but this can never be determined by herd treatment. I am dealing more widely with the general subject in a paper which will be published shortly. I am, Sir, yours faithfully,

Ealing, May 31st. CLAYTON LANE.

TREATMENT OF SCABIES

To the Editor of THE LANCET

SIR,—Dr. Ingram's defence of the use of sulphur in scabies may have some weight in civilian practice, though even here, if more rapid methods prove practicable, the approved societies will consider that the presence of a mite in the skin does not create a sickness disability. Among private patients too there will be some for whom the time factor is very important. The problem however is much more serious in the Army, where one indication of military efficiency is the absence of preventable disease. It is to the Army we naturally look for any advance in disinfestation, as it can command the services of experts in the effects of gases and vapours. To discover the most suitable pesticide for the acarus does not appear a difficult task, at least in theory. The common spider ought, in default of the mite, to make a good corpus vile on which to test the lethal agent. As a dilute sulphur ointment kills (or is it only a repellent?) the parasite, we may conclude that a chemical rapidly fatal to the intruder but innocuous to the host can be found. The crux appears to be the eggs and female in the burrows. Local reduction of the air pressure by rupturing these, as in the treatment of books in a closed chamber, might solve this difficulty, should such arise. A more scientific outlook on scabies would develop if the word were dropped from the Nomenclature of Diseases and classified under such a term as dermatitis infestata. The use of ointments for prolonged periods in skin parasites has had a long day, and the time has come when experience gained in the treatment of infestations outside the human race should receive a fair trial.

I am, Sir, yours faithfully,

Knock, Belfast, June 3rd. R. M. FRASER.

THE INDIAN EARTHQUAKE

To the Editor of THE LANCET

SIR,—The earthquake in Baluchistan is a disaster of the first magnitude. It is inevitable that with a death-roll running into tens of thousands large numbers of children have been injured and orphaned and thrown into want and misery. On behalf of the Save the Children Fund, which during 16 years has disbursed over £2,500,000 for the rescue of children at home and abroad in times of distress and disaster, I am appealing for help for these children. Donations received by the hon. treasurer, Mr. H. D. Watson, C.I.E., C.B.E., at 40, Gordon-square, London, W.C.1, can be used for their immediate relief.

I am, Sir, yours faithfully,

NOEL-BUXTON.

June 4th, 1935. President, the Save the Children Fund.

DISTRESS AND HEALTH.—An annotation of *this* title in our issue of May 4th drew a letter of protest from Dr. John Marrack (vide THE LANCET, May 18th, p. 1189). His criticism was to the effect that in our note upon economic circumstances in relation to the health of the community in Sunderland and certain districts of Durham (H.M. Stationery Office. 1935. Cmd. 4886. Pp. 52. 9*d.*) we had not done justice to the White Paper. In a further communication Dr. Marrack says that the quotation of figures in his previous communication was not correct, but holds that as a correction of the figures would strengthen his arguments his criticism stands good. This is a position which must remain, as Government Departments are unable to enter into public discussions.

THE BIRTHDAY HONOURS

THE list of honours conferred by the King on his 70th birthday contains the following names of members of the medical and dental professions:—

Baronet

Sir Henry Jackson, M.B., M.P.
For services in connexion with transport.

Order of Merit

Sir F. Gowland Hopkins, F.R.C.P., P.R.S.
Professor of biochemistry in the University of Cambridge.

G.C.V.O.

Sir E. Cooper Perry, F.R.C.P.
Consulting physician to Guy's Hospital.

G.B.E.

Sir George Newman, K.C.B., F.R.C.P.
Lately chief medical officer, Ministry of Health and Board of Education.

K.C.B.

Lieut.-General James Andrew Hartigan, C.B., C.M.G., D.S.O., M.B.
Director-general of Army Medical Services.

K.C.V.O.

Lancelot Edward Barrington-Ward, F.R.C.S.
Surgeon to the Hospital for Sick Children, Great Ormond-street, and the Royal Northern Hospital.

A. James Walton, F.R.C.S.
Surgeon to H.M. Household; surgeon to the London Hospital.

K.B.E.

Air Vice-Marshal John McIntyre, C.B., M.C., M.B.
Late director of medical services, Royal Air Force.

D.B.E.

Mrs. Annie Jean Connor, M.D.
For work on maternal and child welfare in Australia.

Miss Constance Elizabeth D'Arcy, M.B.
For work on maternal and child welfare in Australia.

Knights Bachelor

Arthur John Hall, F.R.C.P.
Emeritus professor of medicine in the University of Sheffield.

Walter Burford Johnson, C.M.G., F.R.C.S.
Director of medical and sanitary services, Nigeria.

Patrick Playfair Laidlaw, F.R.C.P., F.R.S.
Pathologist on the staff of the Medical Research Council.

Harry Cuthbertson Moxham, D.D.S.
Federal president of the Dental Association, Commonwealth of Australia.

John Vigers Worthington, M.R.C.S., M.P.
Parliamentary private secretary to the Prime Minister.

C.B. (Military)

Major-General R. B. Ainsworth, D.S.O., O.B.E., M.R.C.S.
Commandant and director of studies, Royal Army Medical College.

Major-General C. W. F. Melville, F.R.C.S.E., I.M.S.
Deputy director of medical services, Eastern Command, India.

Major-General T. G. F. Paterson, D.S.O., M.B., I.M.S.
Deputy director of medical services, Northern Command, India.

Major-General J. W. West, C.M.G., C.B.E., M.Ch.
Professor of military surgery, Royal Army Medical College.

C.B. (Civil)

Lionel Danvers Bailey, M.C., M.R.C.S., K.H.P.
Colonel, Army Medical Services, T.A.; Superintendent of the physiotherapy department, St. George's Hospital.

Surgeon Rear-Admiral J. S. Dudding, O.B.E., M.R.C.S.
Formerly director of medical studies, Royal Naval Medical College.

C.M.G.

David Duff, M.D.
Director of medical services, Gold Coast.

C.I.E.

Lieut.-Colonel Bernard Higham, M.B., I.M.S.
Chemical analyst to the Government of Bombay.

Lieut.-Colonel Robert Knowles, M.R.C.S., I.M.S.
Professor of protozoology and secretary of the Calcutta School of Tropical Medicine; late editor of the *Indian Medical Gazette.*

C.V.O.

Charles Gordon Moore, M.B.
Physician in ordinary to Princess Beatrice.

C.B.E. (Military)

Colonel Wallace Benson, D.S.O., M.B.
Assistant director of medical services, London.

C.B.E. (Civil)

Miss Elizabeth Bolton, M.D.
Senior surgeon to the Elizabeth Garrett Anderson Hospital; dean of the London School of Medicine for Women.

The Hon. A. E. Colvin, M.C., M.B.
Chairman of the New South Wales Hospital Commission.

Cecil Evelyn Cook, M.D.
Chief Protector of aborigines, Northern Territory, Australia.

Hamilton William Dyke, M.B.
Principal medical officer, Bechuanaland.

George Marshall Findlay, O.B.E., M.D., Sc.D.
Member of scientific staff, Wellcome Research Institution. London.

Laurence Edward Keegan, M.D.
Superintendent, General Hospital, Newfoundland.

Robert Edward McKechnie, M.D.
Chancellor of the University of British Columbia.

Charles Johnston Smith, O.B.E., F.R.C.S.E.
Senior surgeon, General Hospital, Singapore.

Michael Herbert Watt, M.D.
Director-general of health, New Zealand.

Miss Millicent Vere Webb, F.C.O.G.
Chief medical officer, Women's Medical Service for India.

O.B.E. (Military)

Major A. J. Beveridge, M.C., M.B., R.A.M.C.
Late medical officer, anti-gas wing, Small Arms School, Winterbourne Gunner.

Major A. G. Harsant, F.R.C.S., R.A.M.C.
Surgical specialist, Egypt.

Wing-Commander T. C. Morton, M.R.C.P., R.A.F.

Surgeon Captain C. F. O. Sankey, M.B.

O.B.E. (Civil)

James Frederick Corson, M.B.E., M.D.
Medical officer. Tanganyika Territory.

George Hugh Culverwell, M.D.
Medical inspector of reformatory and industrial schools, Home Office.

Allan Roy Dafoe, M.D.
For public services as a practising physician in Canada.

Major F. A. Gunasekera, M.R.C.S.
Second-in-command, Ceylon, Medical Corps.

Henry Saumarez Hensman, M.R.C.S.
Superintendent, Government Mental Hospital, Madras.

Miss Helen Mary Mayo, M.B.
For work on maternal and child welfare in South Australia.

Frederick Victor Nanka-Bruce, M.B.
For public services in the Gold Coast.

Dadabhoy Dinshaw Variava, F.R.C.S.E.
Civil surgeon, Aden.

M.B.E.

George Ferguson, M.D.
For work on tuberculosis in Canada.

Mrs. Doris Clifton Gordon, M.B.
For work on maternal and child welfare in New Zealand.

Khong Kam Tak, M.B.
Medical Superintendent, Hospital of Perak Chinese Maternity Association, Ipoh, F.M.S.

Mrs. Helena Muriel Pudney, M.B.
For work on child welfare in Nigeria.

Lieut. John Auty Rogers, M.R.C.S.
Assistant to the Surgeon to the Viceroy of India.

Miss Wenefride Thompson, M.R.C.S.
of St. Luke's Hospital, Chabria, Assam.

Kaisar-i-Hind Medal

Miss Emily Gertrude Stuart, M.B.
of Church of England Zenana Mission Society Hospital, Quetta, Baluchistan.

FORTHCOMING CONGRESSES

MEETINGS which have been arranged for the second half of this year include the following:—

June 27th–29th	National Association for the Prevention of Tuberculosis	Southport.
June 27th–July 3rd	International Congress for Military Medicine and Pharmacy	Brussels.
June 29th–July 3rd	Journées Médicales de Bruxelles	Brussels.
June 30th–July 3rd	International Congress on Physical Education	Brussels.
July 1st–3rd	Maternity and Child Welfare Conference	London
July 3rd–5th	Royal Medico-Psychological Association	London.
July 3rd–6th	Oxford Ophthalmological Congress	Oxford.
July 13th–14th	British Association of Radiologists	Birmingham.
July 15th–20th	Royal Sanitary Institute	Bournemouth.
July 20th–21st	European Mental Hygiene Reunion	Brussels.
July 22nd–27th	International Congress on Accidents and Industrial Diseases	Brussels.
July 23rd–27th	International Congress on Life Assurance Medicine	London.
July 27th–30th	International Thalassotherapy Congress	San Sebastian.
July 29th–Aug. 2nd	International Neurological Congress	London.
Aug. 8th–11th	Gastro-Enterology Congress	Brussels.
Aug. 9th–17th	International Physiological Congress	Leningrad & Moscow.
Aug. 25th–30th	All-Russia Congress of Physiotherapy	Odessa.
Sept. 4th	British Association	Norwich.
Sept. 13th–22nd	Dermatological Congress	Budapest.
Sept. 11th–13th	British Medical Association	Melbourne.
Sept. 12th–19th	Tomarkin Foundation Post-Graduate Course	Brussels.
Sept. 23rd–29th	International Congress of the History of Medicine	Madrid.
Oct. 12th–17th	International Society of Medical Hydrology	Brussels.
Dec. 30th–Jan. 4th	International Society of Surgery	Cairo.

more orderly and methodical use of the roads. The new Highway Code, which Parliament had just approved, if studied and observed, would create a sound road practice. As regarded particular measures, undoubtedly the provision of pedestrian crossings have been responsible for the saving of life and limb. The Ministry managed to get about 10,000 put down in London in three months. He was now making a similar effort in regard to the provinces. It was noteworthy that in London, where the safety measures had been chiefly concentrated, there had been a far greater reduction in accidents than in the country as a whole. There had been a reduction in London in the number of killed of 31 per cent., and of injured 16 per cent. in the last eleven weeks of this year as compared with the same period last year. The reductions for the country as a whole in the last eleven weeks had been 16 per cent. in killed and 11½ per cent. in injured, as compared with the same period last year. The speed limit which came into operation on March 18th had served the purpose of making the flow of traffic more agreeable and smooth. The number of casualties, which had fallen in the City, Metropolitan, and borough police areas by 14½ per cent. as compared with 8 per cent. in country police areas, was a rough indication of its success. In the light of experience he was hoping to de-restrict numbers of roads where the speed limit had been unnecessarily applied.

A most distressing feature of the accident returns was the number of children involved. Of the 3517 pedestrians killed on the roads in 1933 no fewer than 1171, or one-third, were children under the age of 15 years. Two inter-departmental committees had been appointed for England and Scotland to draw up a curriculum for teaching road safety in schools. Undoubtedly, many accidents occurred owing to the lack of playing grounds for children. He had decided on the immediate closing of certain streets in London to motor traffic, except when it was proceeding to premises in those streets. (Cheers.) Notice of a regulation would be given this week converting, as an experiment, certain streets in Southwark and Paddington into children's play streets. It was intended to erect notices at the ends of the streets, and to paint the kerbs with green paint. The system had been tried at Salford and Manchester with success. The intensity of the campaign for road safety, which was the most human part of his task, had coincided with and not in any way checked the rapid extension of the use of the roads by mechanical transport. At the end of February there were 224,000 more vehicles licensed than at the corresponding date in 1934, and 441,000 more than at the same period of 1931. The rate at which new vehicles were coming on the roads exceeded all previous records, and already during the first four months of this year 151,268 new vehicles had been registered. They must do everything that they could to provide for this great expansion, and to see to it that the motor vehicle, like every road-using interest, had all the facilities it could reasonably require from the points of view of both convenience and safety. With this intention in view, the Government decided on a five-year plan for the roads. Highway authorities had been invited to send in their proposals on this basis, and there was every indication that the scope of the plan would be in excess of anything that had been yet achieved in a similar period of time. Considerable progress had been made in the provision of non-skid surfaces, and much experimental work in various parts of the country was being conducted by the Ministry's experimental committee in conjunction with the Road Research Board. The Ministry hoped within five years to eliminate all those weak bridges in the possession of railway and other statutory owners which most seriously affected the free flow of traffic. London experience indicated that the tramcar taken in conjunction with its track had a higher accident ratio than the trolley vehicle, and was a greater hindrance to the free flow of traffic. The number of accidents involving personal injury per 100,000 car miles run was slightly over 6 per cent. in the case of trolley vehicles, and was more than 9 per cent. in the case of tramcars. The London Transport Board had already formulated plans for the substitution of more than 40 per cent. of their tramways by trolley vehicles.

Ribbon Development Bill

After further consideration in the House of Lords on May 29th and 30th, the committee stage of this Bill was concluded without further amendment.

HOUSE OF COMMONS

WEDNESDAY, MAY 29TH

Accidents to Boys Underground

Mr. TOM SMITH asked the Secretary for Mines the number of boys under 16 years of age killed and seriously injured underground during each of the last five years.—Mr. ERNEST BROWN replied: In 1930, 24 boys under 16 years of age were killed and 171 seriously injured below ground at mines under the Coal Mines Act. The corresponding figures for 1931 were 25 and 142; for 1932, 17 and 112; for 1933, 15 and 101; and for 1934, 15 and 122.

Mr. WEST: Does not the Minister think that it is deplorable that children of 14 should be so employed when so many adults are unemployed to-day?

Viscountess ASTOR: Will the National Government try to see whether there is a way of stopping the employment of children under 16 in mines?

Supply of Milk to Hospitals

Mr. LEONARD asked the Secretary of State for Scotland if he would expedite a decision on the part of the committee investigating the milk charges demanded from public institutions.—Sir GODFREY COLLINS replied: I have considered the report, and am grateful to the committee for the care with which they have sifted the evidence and arguments placed before them. It appears to me, however, that any proposal requiring a Marketing Board to give special terms to selected classes of consumers raises wide issues of policy, and cannot well be considered merely as a matter of amendment of an existing marketing scheme. The Committee's views will be carefully examined in connexion with the formulation of a policy for the milk industry following upon the temporary measures brought into operation under the Milk Act, 1934. In the meantime it is not practicable to require the Scottish Milk Marketing Board to give effect to the committee's suggestions.

Mr. LEONARD: Is the right hon. gentleman aware that the hospitals in Scotland last year did not know what charges were being made for milk, and that they are now entering into the second year's contracts in total ignorance of what they have to pay, and is the right hon. gentleman also aware that this may possibly react on the use of grade A, tuberculin tested, milk which may be eliminated as a precautionary measure by some hospitals?

Sir G. COLLINS: I hope that the latter suggestion will not develop. The matter raises large issues of policy, and it has been referred to the Milk Reorganisation Committee, who are at present investigating this and other matters.

Mr. LEONARD: Is the right hon. gentleman aware that the report to which he has referred, and which I presume is in his possession, stated that in so far as these institutions are not receiving special treatment it may be said that the action of the Board is not in the public interest? Is the right hon. gentleman going to countenance something that is not in the public interest? If a reduction in charges is made, can he ensure that the reduction will be retrospective?

Sir G. COLLINS: Preference cannot be given to one institution alone. The Consumers' Committee undoubtedly recommended that that step should be taken, but unfortunately or fortunately, the Milk Marketing Board have no power to single out certain classes of institutions for preferential treatment at the moment.

Mr. PALING: Is it not just as necessary to supply cheap milk to public institutions as to ice-cream vendors?

Sir G. COLLINS: The hon. Member must know that the Government have found large sums of money for supplying cheap milk for children in schools.

Post Office Employee's Death from Anthrax

Mr. Thorne asked the Postmaster-General if he had any information to give to the House in connexion with the death of a Post Office employee from anthrax; whether the cause of death was attributable to his employment; what compensation would be paid to his dependants; and if he had any record of similar cases in his department.—Sir E. Bennett, Assistant Postmaster-General, replied: I much regret to say that a sorter was taken ill and died while on holiday. At the inquest the coroner found that death was due to anthrax, but that there was no evidence as to how the deceased had become infected. The deceased's duties did not bring him into contact with any likely source of anthrax, and there would seem no good reason to attribute his death to his employment. A claim for compensation on behalf of his dependants has been received, but on present information there does not appear to be ground for payment of compensation. A gratuity will be payable under the Superannuation Acts. There is no record of a similar case in the Post Office.

Mr. Thorne: I take it for granted that the man in question was on duty at the time, and that being so, surely there is a moral obligation on the Post Office?

Sir E. Bennett: He was on holiday.

Mr. Thorne: He was in your employ at the time.

Mr. Rhys Davies: In view of the fact that a similar case of death from anthrax occurred at Hull—the man was not in the employment of the Post Office—and they could not find the source of the infection, will the hon. gentleman be good enough to get into touch with the Home Office with a view to tightening up the restrictions upon foreign goat hair?

Sir E. Bennett: That is rather a big order for me; but I can assure both the hon. Members, who have taken an interest in this sad case, that it is by no means closed.

Woman's Detention in West Park Mental Hospital

Mr. Groves asked the Minister of Health if he would make inquiry into the case of a lady, Miss A. C. W., who, on July 22nd, 1932, was committed to West Park Mental Hospital from St. John's Infirmary, Battersea, the only allegation made in her certificate being that she stated that the police were the cause of her losing her job; that she thought they had put out their tongues at her, which she resented, and had prevented her earning her living; and, in view of the frivolous nature of such grounds for certification, would he ensure that a proper and complete investigation was made in all such cases before anyone was deprived of their liberty.—Sir Hilton Young replied: The medical certificates contain other facts besides those mentioned in the question; and the report of the medical superintendent of the mental hospital, made within a few days of the patient's admission, confirmed the view that she needed care and treatment. If the hon. Member desires, I shall be willing to communicate to him, confidentially, further particulars of this patient's mental condition. I cannot accept the suggestion implied in the last part of the question, that a proper and complete investigation was not made in this case by the medical practitioner and the magistrate who dealt with it in accordance with the provisions of the Lunacy and Mental Treatment Acts.

THURSDAY, MAY 30TH

Precautions against Anthrax

Mr. Rhys Davies asked the Home Secretary whether his attention had been called to the recent deaths from anthrax at Chester and Hull; and, if so, whether it was possible to take greater precautions at the ports to prevent the spread of this disease.—Sir John Gilmour replied: Yes, sir, but I am afraid that the information at present available in these two cases does not suggest any further precaution which could have been taken at the ports. In neither case has it been possible so far to establish the source of infection.

Card Room Dust and Public Health

Mr. Sutcliffe asked the Home Secretary what progress had been made by the conference of representatives of employers and employees with regard to the provision of compensation in the event of damage to lungs caused by dust in card rooms in the cotton industry.—Sir John Gilmour replied: I am informed that after some preliminary discussions as to how best to deal with the matter both sides are now seeking certain further information with a view to discovering whether it provides a basis for a practical scheme.

Imported Liquid Eggs and Preservatives

Mr. Glossop asked the Minister of Health if he had considered the reports of several public analysts, to which his attention had been drawn, to the effect that sulphurous acid was being used as a preservative for liquid eggs imported into this country; and what action he intended to take to put an end to this practice.—Sir Hilton Young replied: I have recently received a document in which it is stated that one public analyst has found sulphurous acid in a sample of imported liquid eggs. The enforcement of the Preservatives Regulations is a matter for the appropriate local authorities, but I am making inquiries with regard to this case.

Stassanisation of Milk

Brigadier-General Clifton Brown asked the Minister of Health whether his attention had been drawn to a report of the Danish State dairies on the system of stassanisation of milk as a more thorough and economic way of milk treatment than pasteurisation; and whether he would have inquiry made into this treatment.—Sir Hilton Young replied: I am aware of the report referred to by my hon. friend. Stassanisation is a continuous flow process for the heat treatment of milk, and I am advised that pasteurisation by the holding process efficiently operated gives a greater assurance of the complete destruction of pathogenic bacteria than continuous flow processes.

National Health Insurance

Mr. Sutcliffe asked the Minister of Health whether, in view of the National Health Insurance Bill now before the House, he intended to make known to each one of the 200,000 persons affected thereby exactly what was proposed; and, if so, what steps to that end were being taken.—Sir Hilton Young replied: Considerable publicity has been given through the press and otherwise to the proposals contained in the Bill now before the House, and in particular I am satisfied that they are now well known to approved societies, through whom the insured persons affected can obtain information with regard to the proposals. In the event of the Bill becoming law, steps will be taken to ensure that its provisions are made known by the approved societies to all the insured persons concerned.

Cause of Road Accidents

Sir John Power asked the Minister of Transport if he could state whether it was proposed to publish in respect of 1934 a detailed report on the cause of fatal road accidents similar to the report in respect of 1933.—Mr. Hore-Belisha replied: A comprehensive analysis is being made of all fatal road accidents for the present year, and will be published.

The Selling Price of Milk

Mr. Noel Lindsay asked the Minister of Agriculture in how many districts the Milk Marketing Board had tested the elasticity of demand by varying the selling price of milk; and what was the result of these experiments.—Mr. Elliot: Milk is sold by wholesale on contracts covering the period October, 1934, to September, 1935, inclusive. The contracts do not provide for variation of the retail price of liquid milk, except that on the application of a majority of the retailers in any area the Milk Marketing Board may reduce the minimum appropriate retail price for that area. Reductions have been approved by the Board in about 280 areas, but I have no information so far as to what has been the effect on the demand. The arrangements now in force regarding the supply of milk at special rates to school-children have, I understand, resulted in a very considerable increase in the quantity of milk drunk in schools.

Cheap Milk for Hospitals

Captain Peter Macdonald asked the Minister of Agriculture whether the Milk Marketing Board had considered the possibility of arranging for the supply of cheap liquid milk to the hospitals by means of a scheme whereby all hospitals within a given area would undertake to combine to purchase a regular large daily quantity of such liquid milk; and whether he would urge the Board to deal with this matter as one of urgency.—Mr. ELLIOT replied: The position with regard to the price of milk supplied to hospitals was explained in the reply which I gave to my hon. friend the Member for Bolton, and the hon. Member for the St. Rollox division on May 2nd. I am sure that the Milk Marketing Board would at all times be willing to consider any scheme for the bulk purchase of milk which would be to the mutual advantage of producers and purchasers. Any proposals, such as those which my hon. friend indicates, which the hospitals may wish to suggest should therefore be made direct.

Mr. T. WILLIAMS asked whether the Milk Marketing Board had the power within the existing schemes to sell direct to institutions such as hospitals on the basis of any figures they might agree upon.

Mr. ELLIOT said he understood that in some cases hospitals had already combined in order to purchase milk supplies at the lower rates applicable to milk supplies sold wholesale or in large quantities.

Mr. WILLIAMS asked whether the Milk Marketing Board could sell direct to the institutions without retailers taking any part of the ultimate price.

Mr. ELLIOT: Obviously, that does not arise out of the question.

Infant Mortality in Kensington

Mr. JAMES DUNCAN asked the Minister of Health whether he was aware of the high infant-mortality rate last year in Kensington, 93 per 1000 births as compared with 59 per 1000 for England and Wales as a whole; and if he was satisfied that the Kensington borough council was taking all possible steps to reduce it.—Mr. SHAKESPEARE, Parliamentary Secretary to the Ministry of Health, replied: The answer to both parts of the question is in the affirmative. My right hon. friend understands that the borough council have recently decided to add two whole-time medical officers to their staff, with a view to the further development of the valuable work of the infant welfare centres.

Mr. DUNCAN asked if there was any evidence to show that the deaths of these young children were due to any particular cause, or that the deaths were confined to the children of any particular class, such as the unemployed.

Mr. SHAKESPEARE: No, none at all.

Mr. WEST asked if the hon. gentleman was aware that the death rate in the northern part of the division was 102 per cent., which was the highest in London, and that the chief factors in this terrible mortality were stated to be overcrowding, underground rooms, vermin, and high rents; and if that had not something to do with the borough council.

Mr. DUNCAN asked if it was not the case that the highest death-rate was in a ward of South Kensington, and not in North Kensington.

Sir W. DAVISON asked if the Minister was aware that many of the infants returned to swell this abnormally high death-rate were neither born in Kensington nor died there, and that it was only because of the method of registration of the Registrar-General that they were attributed to Kensington.

Mr. SHAKESPEARE said it was not for him to settle a dispute between the Kensington Members. The plain facts were that the housing conditions in Kensington were bad, and that there was a particularly active council in all matters of housing.

Earthquake at Quetta: Public Health Precautions

Sir S. HOARE, Secretary for India, replying to Mr. ATTLEE, made a statement with regard to the situation at Quetta following on the earthquake. He said that the Western Command had assumed control of the situation and were rationing the population. Arrangements were being made to send food and collect casualties in the villages neighbouring on Quetta. Evacuation was proceeding, and would continue so long as there was no outbreak or epidemic against which all possible precautions were being taken by the medical authorities. Patients were being treated in the Indian Military and Cantonment Hospital, where between 4000 and 5000 had been received up to Sunday evening. Refugee camps had also been established on the race-course. Supplies and personnel were being despatched by train and aeroplane from Karachi and Lahore, and the Viceroy had lent his aeroplane for this purpose. The Viceroy had inaugurated a Quetta Earthquake Relief Fund, and had issued an appeal in India, to which he was sure there would be a prompt and sympathetic response.

TUESDAY, JUNE 4TH

Glasgow Veterinary College

Mr. MAXTON asked the Secretary of State for Scotland whether, having regard to the work done by the Glasgow Veterinary College, he would place it on the same footing as the Edinburgh college as regards Government grants.—Sir GODFREY COLLINS replied: State grants were formerly given to the Glasgow Veterinary College, but as there did not appear to be a need for two State-aided veterinary colleges in Scotland, it was decided in 1923 to discontinue the grant to this college. The decision was subsequently supported by the majority of the Departmental Committee appointed in 1924 to consider and advise regarding the general organisation and finance of agricultural education and research in Scotland. I see no reason for departure from the decision then arrived at.

Malarial Commission in Palestine

Mr. THOMAS WILLIAMS asked the Secretary of State for the Colonies whether there was any likelihood of re-establishing the malarial commission in Palestine.—Sir PHILIP CUNLIFFE LISTER replied: The functions of the Malaria Unit which was, I understand, established under Jewish auspices in 1922, were gradually taken over by the Department of Health of the Palestine Government, and the Unit, as such, ceased to exist in 1930. I have no reason to doubt the adequacy of the staff of the Department of Health for their duties in connexion with anti-malaria measures.

JOINT TUBERCULOSIS COUNCIL.—At the May meeting of this council Dr. C. O. Hawthorne said that a feeding experiment would shortly be commenced in which it was proposed to feed 2000 children on raw milk and 2000 on pasteurised milk. Dr. W. Brand reported 20 participants at the post-graduate course held at Victoria Park Hospital at the end of February. Dr. Peter Edwards has held three courses this year at the Cheshire Joint Sanatorium and proposes a fourth, from July 2nd to 4th. Arrangements for the study tour in Denmark are approaching completion, and Brompton Hospital will give a course from Nov. 4th to 9th. Dr. E. Ward said he had conferred with the College of Nursing and the General Nursing Council about post-graduate study in tuberculosis for nurses. Dr. Tytler and Dr. Edwards promised a note for the next meeting on modern methods of sputum examination. It was suggested that the gasolene concentration method might prove more efficient than culture, as in 4 per cent. of specimens of TB+sputum the bacilli were dead.

NUTRITION ADVISORY COMMITTEE.—The Minister of Health and the Secretary of State for Scotland have appointed an advisory committee "to inquire into the facts, quantitative and qualitative, in relation to the diet of the people, and to report as to any changes therein which appear desirable in the light of modern advances in the knowledge of nutrition." The members are: Lord Luke (chairman), Mrs. Eleanor Barton, J.P., Mr. J. N. Beckett, Dr. G. F. Buchan, Prof. E. P. Cathcart, M.D., F.R.S., Mr. R. R. Enfield, Dr. J. Alison Glover, Dr. J. M. Hamill, Mr. A. Bradford Hill. D.Sc., Sir F. Gowland Hopkins, F.R.C.P., F.R.S., Dr. Donald Hunter, Prof. E. Mellanby, F.R.C.P., F.R.S., Sir John Boyd Orr, M.D., F.R.S., Mr. E. C. Ramsbottom, Mr. J. M. Vallance, Mrs. Chalmers Watson, M.D., Mr. J. R. Willis, and Mr. E. H. T. Wiltshire. The secretaries are:—Mr. W. J. Peete, of the Ministry of Health, London, S.W.1, to whom all communications on the subject should be addressed; Mr. N. F. McNicoll, of the Department of Health for Scotland; and Dr. H. E. Magee, of the Ministry of Health (medical secretary).

MEDICAL NEWS

University of Cambridge

Mr. D. H. Barron, of Yale University, has been appointed university demonstrator in anatomy for three years.

University of London

At a meeting of the senate on May 15th the Dunn exhibition in physiology was awarded to Raymond Dudley Blachford and the Dunn exhibition in anatomy was divided between Alan Graham Apley and Philip Henry Wood. Sir Ernest Graham-Little, M.P., was appointed to represent the university at the celebrations of the 300th anniversary of the University of Budapest (Sept. 25th to 28th), and at the ninth International Congress of Dermatology to be held in Budapest from Sept. 13th to 22nd.

Applications are invited for the Geoffrey E. Duveen travelling studentship in oto-rhino-laryngology and for grants for research in this subject. The Laura de Saliceto studentship for the advancement of cancer research has also to be filled, while the William Julius Mickle fellowship will be awarded to the graduate of the university who has done most to advance medical art or science within the last five years. Particulars of the three appointments may be had from the academic registrar.

A conference for medical officers in industry on leave from the tropics will be held at the London School of Hygiene and Tropical Medicine on July 9th and 10th.

At a meeting of the university court held on May 29th a resolution of thanks was passed to Messrs. Bovril Limited who have instituted at King's College two research studentships in physiology at £350 a year and will defray in addition the cost of the special materials, apparatus, and assistance needed.

Society of Apothecaries of London

A court dinner of the society was held on June 4th in the society's hall, when Dr. Wakelin Barratt, deputy master, presided. The occasion was the presentation to Sir Frederick Banting of the Society's gold medal in therapeutics. Sir William Willcox, senior warden, in presenting Sir Frederick to the deputy master, intimated in warm terms the significance of such a discovery as that of insulin, pointing out the part played in medical progress by such fruitful researches. Sir Frederick Banting, in reply, referred to the scientific activity of his university, the University of Toronto, and spoke eloquently of the closeness of the ties which bound Canada to the mother country in spite of the seductive opportunities offered in the contiguous United States. Sir Frederick Banting's words were received with general applause.

At recent examinations the following candidates were successful :—

MASTERY OF MIDWIFERY

Marie L. P. Crawford, Alice B. Field, Gwendolen E. Kaines, and Mary M. Mackenzie.

University of Wales

At recent examinations the following candidates were successful :—

TUBERCULOUS DISEASES DIPLOMA

Honoria Aughney, Elizabeth M. R. Garrigan, Dorothy M. James, R. A. N. McMath, Nora O'Leary, G. E. Ranawake, K. V. Rao, Amarnath Sah, M. E. Salem, Dhirendranath Sanyal, and A. L. H. E. Sayed.

Society for Relief of Widows and Orphans of Medical Men

At the annual general meeting held on May 22nd, Mr. V. Warren Low being in the chair, the report for 1934 was presented showing that during the year 57 widows and 9 orphans received relief. The sum of £2885 10s. was granted from ordinary funds, £1664 8s. from the Brickwell fund, £80 from the Copeland fund, and a Christmas present amounting to £640. The total income was £5405, total expenses £358. There are now 262 members of the society. Membership is open to any registered medical man who, at the time of his election, is residing within a twenty-mile radius of Charing Cross. Particulars from the secretary, at 11, Chandos-street, London, W.1.

Queen's University of Belfast

The senate of the University has decided to confer the honorary degree of LL.D. on Dr. T. G. Moorhead, regius professor of physic in the University of Dublin; and of D.Sc. on Dr. Thomas Carnwath, senior medical officer in the Ministry of Health, and Colonel W. P. MacArthur, deputy director-general of Army Medical Services.

Indian Medical Service

The annual dinner will be held at the Trocadero Restaurant on Wednesday, June 19th, at 7.15 for 7.30 P.M., when Major-General E. A. Walker, director of medical services in India, will take the chair. Officers can arrange to sit near their friends as separate tables will be provided. Application for tickets should be made to Sir T. Carey Evans at Hammersmith Hospital, Ducane-road, London, W.12, or to Mr. A. W. Brown, c/o Messrs. Grindlay and Co., 54, Parliament-street, S.W.

Royce Research Fellowships

The trustees of the will of the late Sir Frederick Henry Royce created two research fellowships, each of the value of £500 per annum, tenable for three years with a possibility of extension. The subject of investigation is to be the cause and cure either of influenza or of the common cold. It was arranged the University of London should recommend a selected applicant for one of the fellowships whilst the Victoria University of Manchester should act similarly in respect of the other. The trustees have appointed to the London fellowship Dr. Charles Herbert Stuart Harris, whose investigations will be carried out at the British Postgraduate Medical School, Hammersmith. No appointment has yet been made for Manchester.

Mental Hygiene Congress

The third European Mental Hygiene Reunion will be held in Brussels on July 20th and 21st, and it will be followed by a congress of medical alienists and neurologists under the auspices of the Belgian League for Mental Hygiene. The first subject for discussion will be the boarding-out treatment for mental patients, at which Dr. G. Corberi (Milan), Dr. F. Sano (Gheel Colony), and Dr. J. Vié (Aimay-le-Château Colony) will speak. The openers of the second discussion on punishments and restrictions in the family and in the school will be Dr. Heinrich Meng (Basle) and Dr. H. Crichton-Miller (London). The last session will be devoted to a discussion on mental hygiene and the press, to which Dr. O. L. Forel (Nyon) and Dr. J. van der Spek (Rotterdam) will contribute. Further information may be had from the secretary of the National Council for Mental Hygiene, 78, Chandos House, Palmer-street, London, S.W.1.

Liverpool Psychiatric Clinic

At the annual meeting of this clinic, held on May 23rd, at the Rushworth Hall, Miss Martha Jackson of Philadelphia spoke on occupational therapy in American hospitals and clinics, and Dr. R. G. R. Burrows described the work of the Maghull epileptic colony. During last year 232 new patients attended the clinic, making 1483 attendances. This total, although large, is limited solely by lack of staff, and a half-time medical registrar has now been appointed. Of the new patients 83 were women, 68 men 61 adolescents and 20 children: 63 per cent. of the cases were referred to the clinic by their own doctors; 35 per cent. of those attending the clinic are under 20 years. The cases fall roughly into five main groups—nervous disorder 95, mental disorder 56, behaviour disorder 38, mental deficiency 27, organic disease 16. The comparatively large proportion of cases of early mental disorder is regarded as satisfactory for three reasons. First, a proportion can at the outset be recognised as recoverable without resort to drastic measures. Secondly, cases likely to benefit from mental hospital treatment can be brought into touch with its possibility at an early date. Thirdly, there is evidence of a growing demand of the public for mental treatment. By virtue of its independent position the clinic can act as a liaison between the public and its medical service on the one hand and the mental hospitals on the other.

Microchemical Club

The fourth meeting of this club will be held at 11 A.M. on Saturday, July 13th, at the National Physical Laboratory. Lectures will be given by Prof. H. V. Briscoe, Prof. H. D. Kay, and Mr. L. J. Harris, D.Sc. The hon. secretary is S. J. Folley, National Institute for Research and Dairying, Shinfield, near Reading.

All-India Ophthalmological Society

The fourth conference of this society was held at Madras from April 22nd to 24th, under the presidency of Lieut.-Colonel R. E. Wright. The proceedings included a symposium on nutritional disorders of the eye. The discussion centred chiefly around keratomalacia or xerophthalmia, and contrary to views expressed by workers in England and elsewhere, it was held that skin rashes were not considered more frequent in cases of keratomalacia than in the general hospital population, with the exception of lichen pilaris. The same was true of pyogenic infections in general.

British Social Hygiene Council, Incorporated

The annual general meeting will be held during the Imperial Social Hygiene Congress at the London School of Hygiene and Tropical Medicine, Keppel-street, London, W.C.1. The presidential address will be delivered on July 8th, and will consist of a survey of 21 years' work. A business meeting will be held at 2 P.M. on Friday, July 12th. With the notice of these meetings there is a request for members to make known to others the holding of a summer school session at Cambridge. The school will be opened at Westminster College, Cambridge, on July 30th, and will be in session until August 6th; all communications concerning it should be addressed to the secretary of the Council, Carteret House, Carteret-street, London.

Fellowship of Medicine and Post-Graduate Medical Association

A week-end course in infectious diseases will be held at the Park Hospital, Hither Green, on May 15th and 16th, and a clinical and pathological course at the National Temperance Hospital at 8 P.M. on Tuesdays and Thursdays, June 11th to 27th. Other forthcoming courses include: chest diseases at the Brompton Hospital (5 P.M. on Mondays, Tuesdays, and Fridays, June 11th to July 8th); cardiology at the National Hospital for Diseases of the Heart (June 24th to July 6th); "refresher" courses at the Prince of Wales's Hospital (June 17th to 29th and July 1st to 13th); proctology at St. Mark's Hospital (July 1st to 6th); urology at the All Saints' Hospital (July 8th to 27th); medicine and surgery at the Southend General Hospital (July 13th and 14th); and dermatology at the Blackfriars Skin Hospital (July 15th to 27th). A panel of teachers is prepared to give individual instruction in various branches of medicine and surgery, daily. With the exception of the cardiology course, courses and clinics arranged by the fellowship are open only to members and associates. The secretary of the fellowship may be addressed at 1, Wimpole-street, London, W.1.

Medical Diary

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

FRIDAY, June 14th.

Ophthalmology. 5 P.M. (Cases at 4.30 P.M.) Annual General Meeting. Mr. G. T. Willoughby Casbell and Mr. A. Hugh Thompson: A Pedigree Congenital Optic Atrophy differing from Leber's Disease and embracing Four Generations. Mr. Eugene Wolff: The Use of Adrenaline in Atropine and Hyoscine Irritation.

Laryngology and Otology. 9.45 A.M. (Physiological Lecture Theatre, Bristol University). Mr. J. Morris: Electrical Hearing Aids. Mr. W. M. Mollison: Operative Treatment of Vertigo. Mr. C. S. Hallpike: Recent Work on the Electro-physiology of the Mammalian Cochlea. 2.45 P.M., Clinical Meeting in the Out-patient Department at the Bristol Royal Infirmary.

Urology. Visit of the Dutch Urological Society. 10 A.M. (St. Paul's Hospital). Operations and Demonstrations. 2.30 P.M. (St. Peter's Hospital). Operations and Demonstrations.

SATURDAY.

Laryngology and Otology continued. 9.45 A.M. (Physiology Theatre, Bristol University), Mr. E. Watson-Williams: Affections of the Eyeball in Sinusitis. Discussion: Obstructions of the Trachea.

Urology continued. 10 A.M. (Middlesex Hospital), Operations and Demonstrations. 2.30 P.M. (All Saints' Hospital), Operations and Demonstrations.

PADDINGTON MEDICAL SOCIETY.

TUESDAY, June 11th.—9 P.M. (Great Western Royal Hotel, Paddington), Dr. G. E. Oates: Some Housing Problems in Paddington.

RESEARCH DEFENCE SOCIETY.

WEDNESDAY, June 12th.—3 P.M. (London School of Hygiene and Tropical Medicine, Keppel-street, W.C.), Annual General Meeting. Sir Frederick Hobday: The Relief of Animal Suffering. (Stephen Paget lecture.)

SOUTH-WEST LONDON MEDICAL SOCIETY.

WEDNESDAY, June 12th.—9 P.M. (Bolingbroke Hospital, Wandsworth Common), Dr. Robert Hutchison: Constitutional Medicine. (Bolingbroke lecture.)

MEDICAL SOCIETY OF INDIVIDUAL PSYCHOLOGY.

THURSDAY, June 13th.—8.30 P.M. (11, Chandos-street, W.), Dr. A. Baldie: Homosexuality is Detrimental both to the Individual and to Society.

WEST LONDON MEDICO-CHIRURGICAL SOCIETY.

THURSDAY, June 13th.—8.30 P.M. (Kensington Town Hall), Prof. Edward Mellanby, F.R.S.: Proper Feeding, the First Essential for Good Physique and Health. (Cavendish lecture.)

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

MONDAY, June 10th, to SUNDAY.—LONDON LOCK HOSPITAL, Dean-street, W. Afternoon Course in Venereal Diseases.—PARK HOSPITAL, Hither-green. Sat. and Sun., course in infectious diseases.—NATIONAL TEMPERANCE HOSPITAL, Hampstead-road, N.W. Clinical and Pathological Course, Tues., and Thurs., 8 P.M.—BROMPTON HOSPITAL, S.W. Course in chest diseases. Mon., Tues., and Fri., 5 P.M.—Courses of instruction and clinics arranged by the fellowship are open only to members and associates.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C.

THURSDAY, June 13th.—2 P.M., Dr. W. W. Payne: Carbohydrate Metabolism. (3) Influence of the Ductless Glands. 3 P.M., Dr. A. A. Moncrieff: Congenital Heart Disease.

Out-patient clinics daily at 10 A.M. and ward visits (except on Wednesday) at 2 P.M.

INSTITUTE OF CHILD PSYCHOLOGY.

WEDNESDAY, June 12th.—6.15 P.M. (Friends House, Euston-road, N.W.), Dr. Alan Moncrieff: The Effect of Illness upon Temperament. 8.15 P.M., Dr. Margaret Lowenfeld: Play, Phantasy, and Experience.

INSTITUTE OF MEDICAL PSYCHOLOGY, Malet-place, W.C.

WEDNESDAY, June 12th.—3 P.M., Dr. H. Crichton-Miller: Frigidity. 4.30 P.M., Dr. Cedric Shaw: Sexual Difficulties.

SOUTH-WEST LONDON POST-GRADUATE ASSOCIATION.

WEDNESDAY, June 11th.—4 P.M. (St. James' Hospital, Ouseley-road, S.W.), Mr. J. P Monkhouse: Treatment of Suppurative Otitis Media.

INSTITUTE OF PATHOLOGY, St. Mary's Hospital, W.

THURSDAY, June 13th.—5 P.M., Dr. J. Henderson Smith: Virus Disease in Plants: a Comparison with Virus Disease in Animals.

UNIVERSITY OF BIRMINGHAM.

THURSDAY, June 13th.—4 P.M. (Medical Lecture Theatre, University, Edmund-street), Prof. K. Douglas Wilkinson: Acute Rheumatism and its Results. (First of two Ingleby lectures).

FRIDAY.—4 P.M. (Queen's Hospital), Prof. Bertram Lloyd: Demonstration of surgical cases.

Appointments

AINSWORTH-DAVIS, J. C., M.D. Camb., F.R.C.S. Eng., has been appointed Hon. Urological Registrar to St. Paul's Hospital, Endell-street, London.

BARRAN, G. F., M.B. Camb., Second Assistant to the Medical Superintendent at the Liverpool Sanatorium, Frodsham.

BENNETT-JONES, M. J., M.B. Liverp., F.R.C.S. Eng., Hon. Surgeon to the Bootle General Hospital.

DAVIES, A. L., M.R.C.S. Eng., School Medical Officer for Carmarthen.

LOWE, T. E., M.D. Melb., M.R.C.P. Lond., Medical Registrar at St. Mary's Hospital, London.

MCLENNAN, W. A., M.B. Glasg., D.P.H., Medical Officer of Health and School Medical Officer for Leigh, Lancashire.

OSLER, T. G., M.B. Cape Town, Medical Registrar at St. Mary's Hospital, London.

RUSHTON, M. A., M.B. Camb., L.D.S. Eng., Assistant Dental Surgeon, Guy's Hospital.

Certifying Surgeons under the Factory and Workshop Acts: Dr. D. M. HUGHES (St. Clears, Carmarthenshire): H. P. WILLIAMS (Anstey, Leicestershire): Dr. W. DEAN (Wivenhoe, Essex); Dr. A. J. Gibson (Brentwood, Essex); Dr. W. SHAW (Blairgowrie, Perthshire); Dr. R. J. TAIT (Towcester, Northamptonshire).

Vacancies

For further information refer to the advertisement columns

Aberdeen Royal Infirmary.—Sen. Res. M.O.

Albert Dock Hospital, Connaught-road, E.—Res. M.O. At rate of £110.

Aylesbury, Royal Buckinghamshire Hospital.—Sen. Res. M.O. £200. Also Second Res. M.O. £150.

Barnsley. Beckett Hospital and Dispensary.—H.P. £200.

Barnsley County Borough.—Asst. M.O.H., &c. £500.

Bath Royal United Hospital.—H.P. £150.

Bedford County Hospital.—First and Second H.S. At rate of £155 and £150 respectively.

Birmingham, Imperial Chemical Industries, Limited.—Asst. M.O. £500.

Birmingham University, Faculty of Medicine.—Lecturer in Bacteriology and Asst. Bacteriologist in Public Health Laboratory. £400.

Blackburn Royal Infirmary.—Res. Surg. O. £250. H.S. £175. Also Cas. O. £150.

Bolton Royal Infirmary.—Two H.S.'s. Each £125.

Bradford Royal Eye and Ear Hospital.—H.S. £160.

Brighton, Royal Sussex County Hospital.—Two Hon. Dental Surgeons.

Bristol General Hospital.—Two H.P.'s, two H.S.'s. Res. Obstet. O. H.S. to Spec. Depts. Also Cas. H.S. Each at rate of £80.

Bristol University.—Lectureship in Physiology. £400.

Bucks County Council.—Asst. County M.O. and M.O.H. £800.

Burnley, Municipal General Hospital.—Jun. Res. M.O. £150.

Cheltenham General and Eye Hospitals.—H.P. £200.

Chesterfield and North Derbyshire Royal Hospital.—Cas. O. and Fracture H.S. Also H.S. to Ear, Nose and Throat, and Eye Depts. At rate of £200 and £150 respectively.

Colchester Essex County Hospital.—Asst. H.S. £120.

Connaught Hospital, Walthamstow, E.—H.S. At rate of £100.

Derby, Bretby Hall, Orthopædic Hospital, near Burton-on-Trent. Locum Res. Asst. M.O. At rate of £350.

Doncaster Royal Infirmary.—H.S. to Eye and Ear, Nose and Throat Depts. £175.

Derbyshire Hospital for Sick Children.—Res. H.S. At rate of £150.

Dreadnought Hospital, Greenwich, S.E.—H.P. and H.S. Each at rate of £110.

Edinburgh Royal Infirmary.—Clin. Asst. in Dept. of Ophthalmology. £200.

Essex County Council Oldchurch Hospital, Romford, &c.—Asst. M.O. £600.

Fulham Borough Council.—M.O.H. £1,100.

General Post Office, Headquarters Medical Branch.—A.M.O. £500.

Grosvenor Hospital for Women, Vincent-square, S.W.—Gynæcological Surg.

Guildford Royal Surrey County Hospital.—H.S. £150.

Hampstead General and North West London Hospital, Haverstock Hill, N.W.—H.S. At rate of £100.

Harrogate Royal Bath Hospital.—Res. M.O. £156.

Hastings, Royal East Sussex Hospital.—Jun. H.S. At rate of £150.

Hertford County Hospital.—H.S. At rate of £180.

Hull Municipal Maternity Home and Infants' Hospital.—Jun. Res. M.O. At rate of £100.

Ipswich, East Suffolk and Ipswich Hospital.—H.P. £120.

Jersey General Hospital and Poor-law Infirmary.—Res. M.O. £100–£200.

Keighley and District Victoria Hosp.—Res. M.O. At rate of £180.

King Edward VII Sanatorium, Midhurst.—First Asst. M.O. £500.

King's College Hospital, Denmark Hill, S.E.—Asst. Physician.

Lambeth Hospital, Brook-street, Kennington, S.E.—Temp. Pathologist to assist Officer in Charge at Group Laboratory. At rate of £650.

Leeds City Hospital for Infectious Disease.—Med. Supt. £840.

Leicester, County Sanatorium and Isolation Hospital.—Jun. Res. M.O. £250.

Liverpool Royal Children's Hospital.—Hon. Physician.

London Hospital, E.—First Asst. to Gynæcological and Obstetric Dept. £250.

London Skin Hospital, Fitzroy-square, W.—Hon. Physician.

London University.—University Readership in Surgery. £800. External Examinerships. Chair of Dental Prosthetics at Guy's Hospital Med. School. £1000. Also University Readership in Anatomy. £550.

Maidstone, West Kent General Hospital.—H.S. £150.

Manchester Ancoats Hospital.—H.S. At rate of £100.

Manchester Ear Hospital, Grosvenor-square, All Saints.—H.S. Also Res. H.S. At rate of £150 and £120 respectively.

Manchester Northern Hospital, Cheetham Hill-road.—Res. M.O. Also Two H.S.'s. £150 and £100 respectively.

Manchester, St. Mary's Hospitals.—Two H.S.'s for Whitworth-street West Hospital. Also Two H.S.'s for Whitworth Park Hospital. Each at rate of £50.

Manchester, Withington Hospital, &c.—Jun. Asst. M.O. £200.

Marie Curie Hospital, Fitzjohn's-avenue, N.W.—Res. M.O. At rate of £100.

Mitcham, Surrey Wilson Hospital.—Res. M.O. At rate of £120.

National Temperance Hospital, Hampstead-road, N.W.—Cas. O. and H.P. At rate of £120 and £100 respectively.

Newcastle-upon-Tyne, Leazes Hospital.—Two H.S.'s. Each at rate of £100.

Newcastle-upon-Tyne, Royal Victoria Infirmary.—Res. Appointments. Each at rate of £50.

New Zealand, General Hospital, Auckland.—Sen. Surg. O. Also Sen. Med. O. Each £650.

Northampton, County Mental Hospital, Berrywood.—Med. Supt. £900.

Plymouth, Prince of Wales's Hospital.—H.P., Res. Anæsthetist. Also H.S. to Spec. Depts. Each at rate of £120.

Preston and County of Lancaster Queen Victoria Royal Infirmary. Special H.S. At rate of £150.

Princess Elizabeth of York Hospital for Children, E.—H.P. and H.S. Each at rate of £125.

Princess Louise Kensington Hospital for Children, St. Quintin-avenue, W.—H.S. At rate of £100.

Royal College of Physicians of London.—Leverhulme Research Scholarship. £500.

Royal Masonic Hospital, Ravenscourt Park, W.—Res. Surg. O. At rate of £250.

St. Mary's Hospital for Women and Children, Plaistow, E.—Pathologist. £200.

St. Peter's Hospital for Stone, &c., Henrietta-street, W.C.—Clin. Assts. to Hon. Staff.

St. Thomas's Hospital, S.E.—Hon. Registrar to Skin Dept.

St. Thomas's Hospital Medical School.—Demonstrator in Physiology. £400.

Salford Royal Hospital.—Two H.S.'s. Each at rate of £125.

Salisbury General Infirmary.—Res. M.O. £250.

Salvation Army, Mother's Hospital, Lower Clapton-road, N.—Two Jun. Res. M.O.'s. At rate of £80.

Samaritan Free Hospital for Women, Marylebone-road, N.W.—Hon. Surgeon to Out-patients. Also Registrar. £150.

Sheffield Royal Infirmary.—Two H.S.'s. One H.P. Aural H.S. Ophth. H.S. Also Asst. Cas. O. Each at rate of £80.

Shoreham-by-Sea, Sussex, Southlands Hospital.—Asst. M.O. £300.

Somerset and Bath Mental Hospital, Cotford.—Second Res. Asst. M.O. £350.

Southend-on-Sea County Borough.—Med. Supt. for Council's Infectious Diseases Hospitals. £750.

Southend-on-Sea General Hospital.—H.S. to Orthopædic and Cas. Dept. £100.

Stafford, Staffordshire General Infirmary.—H.P. and Cas. O. At rate of £150.

Stirling District Mental Hospital, Larbert.—Jun. Asst. M.O. £300.

Swansea Cefn Coed Hospital.—Asst. M.O. £350

West Bromwich, Hallam Hospital.—Res. H.P. At rate of £200.

West London Hospital, Hammersmith-road, W.—Cas. O. £250. Also H.P. and 2 H.S.'s. Each at rate of £100.

West Riding Mental Hospital, Wakefield.—Fifth Asst. M.O. £350.

Weston-super-Mare General Hospital.—Res. H.P. £150.

Wigan Royal Albert Edward Infirmary and Dispensary.—Res. Med. and Surg. O. and Reg. £250. Also H.S. At rate of £150.

Willesden General Hospital, Harlesden-road, N.W.—Res. Cas. O. At rate of £100.

Windsor, King Edward VII. Hospital.—Res. M.O. £150. Also Three H.S.'s. Each at rate of £100.

Wolverhampton, Royal Hospital.—H.S.'s. Asst. Res. M.O. Each at rate of £100. Also H.P. At rate of £125.

Worksop, Victoria Hospital.—Sen. H.S. At rate of £150.

The Chief Inspector of Factories announces vacancies for Certifying Factory Surgeons at Medbourne (Leicestershire), Portree (Invernesshire), Furnace (Argyllshire). Latest date for receipt of applications June 18th.

Births, Marriages, and Deaths

BIRTHS

BIRCH.—On May 24th, at the Royal Infirmary, Liverpool, the wife of C. Allan Birch, M.D. Liverp., of Hazelwood-court, N., of a son.

HORDER.—On May 25th, at Tunbridge Wells, the wife of Cecil A. Horder, F.R.C.S. Eng., of a son.

MCMICHAEL.—On May 19th, at Vowchurch, Herefordshire, the wife of G. B. McMichael, M.R.C.S. Eng., of a son.

MICKS.—On May 29th, the wife of W. T. Micks, M.B. Dub., of Hull, Yorks, of a son.

MORGANS.—On May 21st, at Bristol, the wife of C. Christopher Morgans, M.R.C.S. Eng., of a son.

RENNIE.—On May 27th, at Colombo, Ceylon, to Jean Marcella Rennie, M.B. Edin., wife of Gilbert McCall Rennie, M.C., Ceylon Civil Service—a son.

WILLIAMS.—On May 30th, at Devonshire-place, W., the wife of Leslie Williams, M.D., M.S. Lond., of a son.

MARRIAGES

GOODCHILD—BARHAM.—On May 14th, at Kabale, Uganda, Roy Theodore Scovel Goodchild, M.B. Lond., to Muriel Mary, elder daughter of the late Harold Barham, of Wimbledon.

DEATHS

BEVAN.—On May 22nd, 1935, Richard Bevan, L.R.C.P. Lond., M.R.C.S. Eng., D.P.H., and Gold Medallist, of 2, Park-avenue, East Sheen, S.W.14, aged 81 years.

BRECHIN.—On May 31st, at the Bensil, Carnoustie, the residence of his brother-in-law, William Adam Brechin, M.C., M.B. Glasg.

HABGOOD.—On May 24th, at Clifton, Bristol, Henry Habgood, V.D., M.D. Brux., late of Eastbourne, in his 87th year.

PURKIS.—On May 30th, at Guy's Hospital, Kenneth Noel Purkis, M.C., F.R.C.S. Eng., of Beckenham, aged 42.

RECKITT.—On May 27th, at Thames Ditton, Lieut.-Colonel John Dennis Thorpe Reckitt, late R.A.M.C., aged 80.

ROSE.—On May 30th, in a London nursing-home, Frank Atcherley Rose, F.R.C.S. Eng., late of Wimpole-street, W.

SHACKLETON.—On June 1st, at Bushey, William Webb Shackleton, M.D. Dub., aged 67.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

NOTES, COMMENTS, AND ABSTRACTS

UNFIT HOUSES

A CREDITABLE commentary on Part II. of the Housing Act, 1930, which deals with the repair or demolition of individual insanitary houses, has been compiled by Mr. H. G. Clinch, F.S.I.A., and Mr. B. G. Bannington.[1] In considering the need of defining "fitness," they state that the position is so unsatisfactory that at the Sanitary Inspectors' Conference, 1934, the opinion was expressed that "minimum standards of fitness should be laid down by housing legislation." Yet on the preceding page the authors themselves admit that "what (standard) would be normal and reasonable in a big town would be infrequent and perhaps impossible in many villages." The authors apparently realise the impossibility of laying down hard-and-fast standards for the country generally.

A number of pages are devoted to standard specifications dealing with repairs and alterations to dwelling-houses, and the reader is invited to follow the "procedure set out with appropriate variations when dealing with houses under Sections 17, 19, and 20 of the 1930 Act." These specifications deal with practically everything in a dwelling-house from the chimney-pots down to the foundations, but omit reference to ventilated food storage accommodation, vermin, and paintwork; yet food must be stored somewhere, preferably in a cool ventilated place; houses should be free from vermin; and paint is necessary to preserve and maintain dwellings in proper condition. In their prefatory remarks, the authors state that Part II. is "full of pitfalls into which even the wariest may slip." Lest this and other comments should discourage inexperienced officers from making use of valuable legislation, it is important to emphasise the fact that sufficient experience of this legislation has been obtained and made available in "case law" and elsewhere, to enable officers of local authorities to use with success this strong weapon against bad housing conditions.

ALLERGIC DERMATOSES

A TENTATIVE classification of allergic dermatoses is suggested by Sulzberger, Wise, and Wolf, who illustrate it in schematic and tabular form (Jour. Amer. Med. Assoc., April 27th, 1935, p. 1489). The first three groups in their classification relate to the eczematous, the tuberculin and the urticarial reactions. Each has its particular "shock tissue," its type of lesion, time factor, and characteristic test—e.g., the patch and scratch tests. They point out that there tends to be a common factor in the causative agents in each group; thus substances producing eczematous reactions tend to be keratolytic or to have an affinity for epidermal tissues. The fourth group is a miscellaneous one, including drug and other reactions, and awaits further elaboration. The authors themselves would probably agree that no such classification can be rigidly adhered to, but it is likely to be helpful as indicating certain broad features in these reactions and in pointing to lines of investigation.

PRESCRIBING IN BRISTOL

A PHARMACOPŒIA, issued jointly by four Bristol voluntary hospitals, contains a comprehensive range of formulæ. It has been revised in accordance with the B.P. 1932 and brought up to date. The ingredients are given in full Latin and the quantities in the imperial system, with no mention of metric equivalents, even for substances like *neoarsphenamine* and sulpharsphenamine which are always prescribed metric. The formulæ are a curious mixture of ancient and modern. Mistura Coryzæ (p. 24) contains ten different ingredients, a perfect example of polypharmacy, and the formulæ for Mist. Acid. Acetyl-salicyl. Citrata, Pulv. Strontii Lactat. Co., and Syrup. Camph. Co. appear unnecessarily complicated. On the other hand, the salicylic ester of dihydroxy-ethane ("S.E.D."), a comparatively new synthetic, is given a short monograph to itself and is used in two liniments. Only two formulæ for compressed tablets are given and 19 for pills. This is against the trend of modern hospital practice where pills are being largely displaced by tablets. The section entitled Treatment of Poisoning is excellent, but it is rather startling to see sulphonal and trional included here among the barbiturates. A list of synonyms would have been more useful if the well-known trade names were alphabetised rather than the lesser known chemical names. Mistakes are rare and trivial and the booklet contains much of value for the practitioner. It is printed for private use but may be had (3s.) from the secretaries of the Infirmary, Hospital, Children's Hospital, and Eye Hospital.

CIRCULATION AND LUNGS

AT the eighth meeting of the Deutschen Gesellschaft für Kreislaufforschung, held at Wiesbaden in March, the communications included a number of interesting papers on the physiology of the circulation. In particular, problems of the relationship of respiration to the cardiovascular system were discussed. W. R. Hess (Zürich), speaking on the respiratory changes brought about by changes of blood pressure acting through nervous stimuli from the heart, aorta, or carotid sinus, emphasised that the respiratory centre cannot be regarded as the only primary governing control for the regulation of respiration. M. Hochrein (Leipzig), dealing with œdema of the lung, stressed the need for treatment of the respiratory mechanism, and of the nervous system. With other speakers he referred to the beneficial effects of luminal in this condition. The numerous important reflex effects upon the circulation from other organs were exemplified by the account of the "feeding reflex" which leads to an increase in the cardiac output after the intake of food. E. Reinhardt (Berlin) described atelectasis, or collapse of lung, as mainly due to reflex contraction of the muscle-fibres in the lung tissue, and emphysema as a widening of the alveoli and acini following a lowered excitability of this muscular tissue. In the former the result was hyperæmia with exudation and fibrosis; in the latter it was ischæmia with actual disappearance of alveolar walls. Acute massive collapse he regarded as a nervous contraction of the bronchial muscle of reflex origin.

Among a number of other subjects considered may be mentioned the use of carbon dioxide for intermittent claudication and endarteritis. A favourable report was given on the effect of this gas injected subcutaneously in such conditions.

T.C.P. B^3 COLLOIDAL EMULSION (British Alkaloids Ltd., Winchester House, London, E.C.).—Some five years ago a note on this preparation was made in THE LANCET, and a later reference to the contents and doses of the preparation will be found in our columns of April 23rd, 1932, p. 918. We have now received from the manufacturers three brochures, setting out that the emulsion has been found of value in the treatment of bacillary dysenteries and intestinal toxæmia, while with a slight alteration in composition it has proved of service in the rheumatoid diatheses. This would be expected, as disinfection of the intestinal tract is a regular procedure in the treatment of many conditions which fall under the denomination of rheumatic or rheumatoid. In all three brochures there is careful reference to recognised authority for the statements and deductions.

ADDRESSES AND ORIGINAL ARTICLES

FURTHER OBSERVATIONS ON LUNG ABSCESSES AND THEIR TREATMENT

By A. J. Scott Pinchin, M.D., F.R.C.P. Lond.

SENIOR PHYSICIAN TO THE CITY OF LONDON HOSPITAL FOR DISEASES OF THE HEART AND LUNGS, VICTORIA PARK, AND TO HAMPSTEAD GENERAL HOSPITAL; PHYSICIAN TO THE WEST LONDON HOSPITAL; AND

H. V. Morlock, M.C., M.D., M.R.C.P. Lond.

PHYSICIAN TO THE CITY OF LONDON HOSPITAL FOR DISEASES OF THE HEART AND LUNGS; ASSISTANT PHYSICIAN TO THE MILLER GENERAL HOSPITAL AND TO HAMPSTEAD GENERAL HOSPITAL

If excuse be needed for a further paper on this subject we may quote an annotation from this journal on a series of papers dealing with abscesses of the lung: "From small collections of clinical impressions such as these it may become possible in time to obtain an individual experience which will bring to bear at the right moment all the weapons available for use in this distressing condition." At present the expressed opinions of authorities differ *toto cœlo*, and in consequence it is difficult to assess treatments adequately.

These tentative views and uncertainties will be appreciated by those who have followed the discussions at the Royal Society of Medicine and elsewhere. It appears to us that a great deal of this hiatus is due to the lack of adequate classification of the various *types* of the disease, each of which requires a different method of attack. During the past five years we have spent much time in investigating such cases and have collected a series of 100. In October, 1930, we described in this journal 27 cases treated medically and surgically; the results left much to be desired, and at the end of that year we started our bronchoscopic clinic. In 1932 we recorded a further 25 cases treated bronchoscopically, and here the results were so satisfactory that we were encouraged to continue. During the past two years a further 55 cases have been through our clinic; these have been sent from all over the country and in various stages of the disease, mainly rather advanced. On the experience gained from this increasing number of cases we have somewhat modified the opinions on treatment which we have previously set out, and in this paper we propose to state our present views, with the full realisation that further experience may cause their further modification.

Classification

The diagnosis of the ordinary type of lung abscess has been sufficiently ventilated elsewhere, and on this occasion our concern is with those cases difficult of diagnosis and more especially with recognition of the *type* of abscess present, as a lead to prognosis and the best method of treatment. Generally it may be conceded that in a case of lung abscess, after pus has been expectorated, the symptoms are of more importance than the physical signs; before this X rays are of more help than either.

We have no knowledge of interstitial abscess, but in our experience it is rare for an abscess to attain any degree of maturity without some periodic discharge from the bronchus.

In considering the pathological types of abscess it is usual to divide them into "acute" and "chronic," whilst some authors make a special feature of the gangrenous type. This classification is certainly not an adequate one on which to base treatment. The division of acute and chronic is an arbitrary one, depending to some extent on the rapidity of breaking down, but more commonly on a time factor, the condition being regarded as acute for the first eight or ten weeks, after which it automatically becomes chronic. We are of the opinion that the classification should be more elaborate and suggest some such division as the following.

1. Pre-abscess stage of pneumonitis.
2. Pyogenic type
   - Simple (with or without localising reaction).
   - Gangrenous or liquefactive type.
3. Putrid or spirochætal type
   - Secondary to simple.
   - With local reaction.
   - Fulminating gangrenous.
4. Multiple: Simple pyogenic or gangrenous.

A definition of the reactive conditions mentioned is necessary.

On X ray examination the simple abscess begins as an homogeneous shadow in the lung field; this may clear up, but usually, later, in the centre of this is seen a darker circular area due to cavitation. At this stage any of three things may happen: (*a*) the cavity after drainage may close and the area of pneumonitis disappear; or (*b*) the area showing cavity may rapidly extend until the whole area affected by pneumonitis becomes a cavity—which may be enormous. This we would define as the liquefactive or simple gangrenous type. Lastly, (*c*) the cavity may remain but may be surrounded by a condensed area of tissues recognised in radiograms as a limiting ring.

The putrid or spirochætal type, if primary, breaks down rapidly and the X ray picture is similar to that of the acute spreading pyogenic type, except that the general condition of the patient is worse; however, if the spirochætal infection is secondary to a pyogenic abscess there is often a primary localising reaction and the progress may not be so acute.

A patient with lung abscess is usually very ill, but occasionally the systemic symptoms may not be at all conspicuous; especially is this so in apical abscess with good drainage. Except in these milder cases the disease appears to have a serious effect on the psychological state of the patient and loss of morale is often a very marked feature. The temperature is usually of a high grade with a rapid pulse, but when the pus has discharged either naturally or by drainage the temperature and pulse-rate fall. A continuous high or rising pulse-rate, even though the temperature is slight, is usually an indication of a spreading non-localised type of disease with a bad prognosis apart from surgical intervention.

It must be borne in mind that the simple abscess in its earlier stages may present periods of normal temperature and no sputum, giving the erroneous impression that healing has occurred—a hope shattered by an exacerbation and further expectoration of pus. A fact of even more importance is that the abscess may be spreading whilst the patient shows no systemic symptoms.

Though the patient with a simple lung abscess may be a sick man, his state is nothing in comparison with the profound toxæmia met with in the true gangrenous type. Seldom is a patient seen so utterly ill as in this condition; a persistent high temperature, rapid thready pulse, constant expectoration of nauseously offensive sputum, and a terrible depression of mind are the distinguishing features, although all our cases have had similar physical signs—viz., the abscess has been basal or posterior, the percussion note dull or tympanitic with marked bronchial breathing and absence of added sounds, the sputum particularly offensive, and of a typical green-brown appearance.

Bronchoscopy in Diagnosis

Bronchoscopic investigation is essential in every case and will reveal the position of abscess, the type, the presence of foreign body or growth (simple or malignant), and the presence of a pressure obstruction (not uncommon in upper lobe abscess) due to glands —tuberculous, malignant, or inflammatory. Absolute reliance cannot be placed on a *negative* X ray film, especially in any case clinically suggestive of abscess; and in this type of case simple lipiodol examination by any of the ordinary routes may be of no use, as it is recognised that lipiodol given this way seldom enters an abscess cavity owing to œdema of the mucous membrane of the bronchus of drainage. On several occasions with negative X ray findings bronchoscopy has shown us pus coming from one of the branch bronchi, and a bronchoscopic lipiodol has proved the presence of an abscess; this occurs especially in those cases which present in X ray antero-posterior view near the mediastinum or in relation to the diaphragm in a mesial position; the bronchus of drainage in these cases being the dorsal branch or the terminal internal and posterior branches of the lower lobe bronchus. If surgical intervention should become necessary the *exact* position of the abscess must be known. Those who have witnessed at operation a search for an imperfectly localised abscess and have seen the disappointing results from insufficient drainage will appreciate the difference when the abscess is accurately located, opened at the first incision and drained from the point of greatest advantage.

FIG. 1

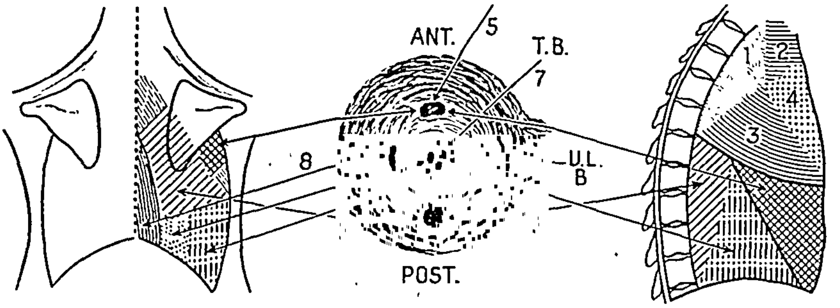

FIG. 2

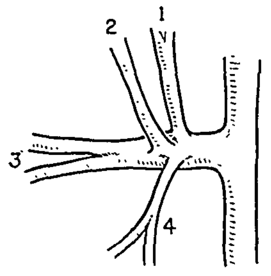

FIG. 1.—Diagram of bronchial tree viewed through bronchoscope. The numbers 1–4 relate to the upper lobe bronchus (U.L.B.) and are explained in Fig. 2. 5 = middle lobe bronchus. 6 = dorsal bronchus. 7 = terminal bronchi, going to lower lobe (anterior, posterior, and axillary). 8 = cardiac branch.

FIG. 2.—Upper lobe bronchus. 1 = posterior apical branch. 2 = anterior apical branch. 3 = transverse axillary branch. 4 = anterior pectoral branch. The numbers on the right of Fig. 1 indicate the corresponding areas of the lung.

Even if postural drainage is to be employed this cannot be efficient unless the bronchus which is draining the abscess has been determined. In many cases the abscess is not seen in the X ray as a definite cavity or, if seen, is surrounded by an area of pneumonitis or fluid which obscures the optimum point of attack. Physical examination and radiology alone cannot be depended on for accurate localisation, they only give a rough indication and, as mentioned above, may fail to disclose an abscess at all.

Topical diagnosis by means of the bronchoscope is done in two ways. First by careful search of the bronchial tree, noting the branch down which the pus is coming. (Reference to Figs. 1 and 2 will show the relationships of the branches to the pulmonary parenchyma.) Secondly, by injection of lipiodol up the branch from which the pus is coming, followed by radiography. The amount of lipiodol used must be judged on the suspected size of the cavity; overfilling is to be avoided, but a large gangrenous cavity needs a large amount to outline borders.

Radiograms must be taken antero-posterior, postero-anterior, and lateral, and upright as well as prone, for it is sometimes difficult to distinguish an alveolar filling from a cavity, and a fluid level seen in the upright is a great help in this differentiation. An important point is that bronchiectasis may be shown, precluding a cure by medical means. A thorough bronchoscopic search must be made, each bronchial branch being examined methodically with the telescope. No atropine should have been given before, as it may dry up the secretions so that no discharge may be seen.

If, for example, we take the right side, in the upper lobe bronchus the pectoral branches can be seen by slight movement of the head to the left, the transverse axillary branch by slightly more deflection, whilst the anterior and posterior ascending branches are shown by use of the retrograde telescope; thereafter search of middle, cardiac, and terminal lower lobe bronchi is easy. Overflow into lower bronchi may cause difficulty, but by cleaning out secretion and making patient cough the site can usually be ascertained.

Those cases with empyema and broncho-pleural fistula may give rise to some difficulty in differential diagnosis. When lipiodol is injected through the bronchoscope it sometimes happens that a small quantity enters the empyema cavity, clinching the diagnosis; in others the fact that the lipiodol in the lung fails to extend as far peripherally as the chest wall will suggest the presence of fluid. In two cases this has proved useful in diagnosis.

Therapeutic Bronchoscopy

We shall now consider whether bronchoscopy has a place in the treatment of pulmonary abscess. There can be no possible doubt that its value in diagnosis both as to the type and the position of abscess is so great that treatment without it cannot be justified.

Treatment must be considered both from the pathological and the anatomical standpoint, the areas affected to be taken in the following order.

Apical.	Upper lobe.
Peripheral.	In any lobe.
Mid zone.	
Hilus.	
Basal or diaphragmatic.	

There is a considerable difference of opinion as to the frequency with which an acute abscess clears up on medical treatment with postural drainage, figures varying from 10 to 60 per cent. In our first series the proportion of cases was 60 per cent., but in our latter series, however, it has been very small; the majority of our cases have a history of more than two months, and the fact that they are mainly segregated cases renders comparative figures unreliable.

Whatever the figure may really be—if only 40–50 per cent. of acute abscess or pneumonitis break down or become chronic—we should certainly try to prevent this happening. It has generally been advocated, and in the past we have supported this view, that an abscess or suspected abscess may be treated medically for two months before more active measures are taken. It would, however, seem *inadvisable and not in accordance with medical* teaching to wait for an abscess to form before starting treatment to abort it, which may in our opinion often be done.

We believe bronchoscopic drainage and instillation of Gomenol is often successful in causing resolution at this stage. To wait on an incipient abscess because it may resolve is to risk a large abscess occurring before it is realised; not uncommonly these are apical and difficult to treat. No harm can come of bronchoscopic treatment which, if successful, may save the patient a serious operation.

For effective bronchoscopic drainage a definite technique is required. The drainage-tube *must* be passed *up* the branch bronchus of drainage; it is often found that even so no pus can be evacuated. It is impossible to insert the ordinary drainage-tube more than 1 or 2 inches, with the result that when suction is applied the distal walls of the tube close and prevent aspiration (Fig. 3). With our operating bronchoscope we can introduce a catheter which will sometimes pass 4–5 inches up the branch bronchus, and can be seen radiographically entering the abscess cavity. The casual introduction of a drainage-tube is useless, except in cases in which there is a great possibility of the condition healing naturally.

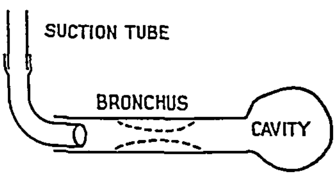

FIG. 3.—Diagram illustrating closure of bronchus by suction when ordinary drainage-tube is inserted.

For lavage and disinfection we have tried various substances—T.C.P., eusol, weak solution of novarsenobenzol, and a dye solution of acriflavine and gentian-violet as recommended by Kolmer. On the whole we have found our original preparation of 10 per cent. gomenol oil in olive oil or lipiodol with normal saline for lavage the most satisfactory. If the bronchus be obstructed by granulations or hæmorrhage is occurring, as is not uncommon in a healing abscess, silver nitrate solution is applied locally.

The necessity of early treatment in infective conditions to prevent serious consequences and the gangrenous type of infection is exemplified in infected foreign bodies, some of the worst cases being infected teeth lost down the trachea, pieces of tartar inhaled at operation, or peanuts. Very soon after inhalation infection spreads, and within a week two zones may usually be seen in a radiogram. A zone of collapse and external to this a zone of pneumonitis, the latter tends rapidly to break down and infect the collapsed area, and in consequence a large and usually gangrenous type of abscess is formed in a short period. A similar condition may also be seen in a bronchus obstructed by new growth.

CASE 1.—Sent to us a week after loss of tooth down bronchus followed by hectic temperature 24 hours later. Radiography: area of collapse and pneumonitis. Tooth removed, infected area swabbed with clove oil, immediate fall of temperature. Two days later following respiratory exercises to expand lung, the temperature rose to 101°, settling gradually within week. No further symptoms.

CASE 2.—Admitted three weeks after inhalation of tooth. This patient had a gangrenous abscess and died soon after admission, which emphasises the necessity of early treatment in all such cases.

The spirochætal gangrenous abscess or the pyogenic gangrenous type.—In these cases medical or bronchoscopic treatment is useless and dangerous because of the delay it causes. Bronchoscopy should be done once to fix the site of the abscess with lipiodol, and then again the day before operation to empty the cavity in an attempt to prevent post-operative inhalation of the abscess contents. This drainage often greatly improves the condition of the patient and the temperature may fall; but one must not be led astray by it, as this type of case can only be dealt with by surgical procedure, the rising pulse-rate usually indicates all is not well, and the operation should be done whilst the improvement is present.

We have had seven cases of this type: four acute gangrenous, two chronic gangrenous, and one pyogenic gangrenous. In 1 of the gangrenous cases the patient died within 48 hours of admission; 3 acute and 1 chronic were surgically drained soon after admission. All died. One chronic gangrenous of one year's duration had two bronchoscopic drainages with operation, and after progressing for six weeks died of hæmorrhage. The pyogenic case had a three months' history, was drained bronchoscopically three times, and operated on, the position of the abscess was exactly defined, and patient made a good recovery. Cases such as these must be treated surgically at the earliest possible moment to avoid their becoming chronic.

Simple pyogenic type.—In these cases bronchoscopic drainage will usually effect a cure. In the gangrenous type bronchoscopic drainage may be successful, the number of treatments necessary may vary from 2–3 in acute cases to 50–60 in chronic. On the whole the progress of cases with well-marked local reaction is better, despite the statement of some authors that after fibrosis has taken place open operation is the only treatment and the result of operation is rendered less favourable. When there is no localising reaction and the condition appears to be spreading, as seen radiologically, even although drainage may be adequate and the temperature has fallen, a rising pulse-rate is an indication for considering surgical treatment.

The necessity for absolute rest, and sanatorium régime for these patients, whether under postural or bronchoscopic drainage, cannot be overstressed. After a few bronchoscopies the patient usually feels well; temperature and pulse are normal, weight is gained, and sputum reduced to little or none. But the cavity is still patent though clean, and if the patient is allowed to go out of hospital there is usually a recrudescence. The warning does not apply to the patient with chronic abscess, refusing surgery, in whom drainage is being conducted as a palliative measure.

The mere fact of recurrence in a "cured" case does not negative further bronchoscopic treatment.

CASE 3.—Large abscess of some months' duration. Five bronchoscopies; healed. A year later relapse; abscess same size. Three bronchoscopies; healed and has remained well (26 months) up to date.

It is important that the benefit from bronchoscopy should not blind one to the fact that in chronic cases complications may occur, such as bronchiectasis associated with the abscess, and the patient may be cured of his abscess and left with bronchiectasis. Enthusiasm must be tempered with judgment. That the patient with chronic abscess with bronchiectasis can be kept fairly well by this means is proved by five patients with bronchiectatic abscesses who do their work and have had occasional lavage for four years and refuse any other treatment.

In those cases of new growth simple or malignant complicated by abscess the condition of the patient may be much improved and rendered more comfortable by drainage and insertion of radon to render the bronchus permeable. A man has attended our clinic for three years with a recurrent (? simple) growth of left upper lobe whose abscess was cured in this way. We have used radon and drainage with success in this way not only in malignant cases who have an abscess but as a prophylactic in cases without abscess in whom there is no hope of permanent cure.

These principles in the treatment of abscess must be modified according to its situation. The apical upper lobe abscess is unfortunately fairly common and though the condition of the patient may not be so bad if drainage is free, the prognosis is not so good owing to difficulties of drainage both bronchoscopically and surgically. Bronchoscopically it is difficult to drain on account of the mechanical problem of getting a drainage-tube up the branch bronchi, as may be seen by the diagram (Fig. 2). This can be achieved by means of a curved steel spring stilette in a gum-elastic catheter and the operating bronchoscope, but is not easy. Surgically they present difficulties of approach.

Owing to the rigidity of the upper part of the chest and the smaller amount of surrounding lung tissue it has not the same opportunity of compression by healthy lung as those lower down. Despite these difficulties they may sometimes clean up in a surprising manner.

CASE 4.—Five months' history. Right upper lobe abscess size of golf ball with well-marked wall. Completely healed after four bronchoscopic drainages.

CASE 5.—Right upper lobe; four months' history; good progress after ten bronchoscopies, but wanted operation. Open drainage. Recurrence after six months, now again on bronchoscopic drainage. Condition good but abscess still patent.

CASE 6.—Right upper lobe; one year's history during which abscess had appeared to heal on medical treatment. Recurrence. Two bronchoscopic treatments followed by rapid healing.

Peripheral type.—By this is meant abscesses in close proximity to the pleura in any lobe. The chance of infection of the pleura causing a local empyema or rupture of the abscess with infection of the whole pleura is very real. Attempts to collapse with artificial pneumothorax, done in error, owing to the abscess being mistaken for a tuberculous infiltration, cause infection of the whole pleura.

CASE 7.—Was admitted to sanatorium with what was supposed to be an early apical lesion. Artificial pneumothorax was induced and followed by hectic temperature. It was realised that an abscess had been collapsed and patient was admitted to Victoria Park Hospital. A free empyema was drained and after several months' severe illness patient made a good recovery.

Mid-zone abscesses in the middle third of lung field are in communication with larger bronchi and are very suitable for bronchoscopic drainage. There is little fear of infection of pleura and there is plenty of adjacent lung tissue to help close the cavity.

Hilus region.—These are even more accessible to bronchoscopic treatment. This is the type of case in which artificial pneumothorax has been specially recommended, but it is hard to collapse a tuberculous cavity in this situation and to obtain complete collapse in abscess is still more difficult.

CASE 8.—Four years ago an abscess at right root which lipiodol would not enter. Treated for two years with artificial pneumothorax, during which time patient very ill though about. A.P. stopped two years ago; lung now out. Cavity still present; lipiodol enters. Patient in good health but a dry cavity is still present. We agree with Kindberg and Monod, who state that if A.P. is done it may have to be continued indefinitely.

Basal type.—These are often as difficult to treat as to diagnose; they are often inaccessible to surgery and may be mistaken for subphrenic abscess as they are often accompanied by elevation of the diaphragm. Bronchoscopic drainage is the best method of treatment.

CASE 9.—Seen four years ago with a 16 months' history. He was surgically explored and nothing found; phrenic avulsion and A.P. were both of no avail. A bronchoscopic lipiodol showed a cavity in angle of diaphragm and mediastinum. This patient had about 30 bronchoscopies and has now been well for two years.

CASE 10.—Appendicectomy in a general hospital followed by fever and pain low on right side with elevation of diaphragm. Subphrenic abscess suspected; needling negative. Temperature settled and he left hospital. Within a week had an hæmoptysis and was admitted to Victoria Park Hospital. Bronchoscopic lipiodol showed abscess right base. Treated by bronchoscopic drainage and sent to convalescent home; returned with pleural involvement; open operation confirmed lung abscess. Cure.

Surgical Measures

Failing bronchoscopic drainage we have to consider the other methods available for those cases which have not cleared up with medical treatment.

The high operative death-rate in primary operation is serious and a risk the physician is disinclined to take unless it be absolutely necessary. We feel, however, *that if the patient be adequately prepared* for the surgeon by drainage, localisation, &c., and be operated on at the most suitable time the results might be very much improved, and our cases referred to surgeon show this. The most suitable cases for surgery *are those in which the bronchus of drainage* is the dorsal branch of the lower lobe bronchus whose area of supply is posterior and below scapula.

In cases which have been submitted to open operation the bronchoscope is useful as a means of washing out the infected zone from above; this may be continued by instillation with gomenol through a laryngeal catheter.

CASE 11.—Post-tonsillectomy abscess of one year's duration. Bronchoscopic drainage rapid improvement. After some months, ill-advisedly sent for a change, came back much worse. Operation advised. First operation unsatisfactory. Second operation modified cautery lobectomy. Condition continued bad till washing from above was employed, after this rapid improvement and patient has now left hospital on occasional lavage, with very slight discharge of sputum.

The above remarks apply to incision of abscess; the figures for lobectomy in this complaint have been too bad for serious consideration in the past, but with improving surgical technique in this direction it is possible that in the near future this will be considered the best treatment for lower or middle lobe abscess complicated with a residual bronchiectasis.

Phrenic avulsion.—Sporadic and isolated reports on the cure of lung abscess by this means appear from time to time, and it is suggested that it helps by completing drainage when this is free. We have, however, to face the fact that drainage usually is not so free after this operation owing to kinking of the bronchus. Therefore we do not use it, nevertheless we agree that it may have a definite use if bronchoscopic drainage is continued after the operation has been done, but probably a phrenic crush is more advisable than avulsion of the nerve; this was brought to our observation by two cases of abscess which were referred to us after phrenic avulsion had been performed at a general hospital. After the operation both patients had become much worse, but both were treated with regular bronchoscopic drainage and although one of them had more than one abscess they rapidly improved, healed, and have remained at work for three years.

Encouraged by these results we tried phrenic avulsion on a case of lung abscess, healed by bronchoscopic drainage, which had a residual bronchiectasis which was not improving on the treatment. After the operation he was allowed to go home and went steadily downhill, lost 2 st. in weight, and was spitting 15 oz. a day. However, on the resumption of bronchoscopic drainage in hospital he rapidly gained more weight than he had lost and sputum was reduced to a trace.

Plastic operations on the chest wall are much the same in their result as phrenic avulsion and we now never advise them.

Artificial pneumothorax.—In the majority of cases to induce a pneumothorax means the production of an unlocalised empyema, and the feeling in this country is adverse to this, except possibly in the hilus case, to which we have mentioned an objection above. Nevertheless certain continental authorities have suggested producing an empyema in this way as a means of a cure.

We are bound to say that in those cases in which this complication has arisen—whether the artificial pneumothorax and empyema has been produced advisedly, in error (as in the case quoted above), or as a sequel to bronchoscopic treatment—the ultimate result has usually been cure of the abscess. The patient, however, has such a stormy passage and often seems so near death that one hesitates to initiate the condition. Moreover we have found that empyema secondary to bronchoscopic treatment tends to be circumscribed and of better prognosis; and we do not regard it as a much-to-be-regretted complication.

Results

Of the 55 cases, 8 were admitted in a condition in which no treatment could avail. The duration of the disease was mostly over three months, the shortest being three weeks and the longest one year. Palliative operations were undertaken in some of these cases, but for obvious reasons they are not included in surgical results.

Of the remaining 47 cases, 2 were submitted to immediate operation. A woman who had refused all treatment for a year was admitted with a secondary empyema which was drained. She recovered from the operation but died later of cerebral embolism. Recovery took place in one case of pyogenic gangrenous type, with a three-months' history, treated by lobotomy. The remaining 45 cases were considered suitable for bronchoscopic treatment. The five youngest were aged 4, 6, 7, 13, 14, and all of these recovered. Three (6·6 per cent.) died whilst under treatment. One who had been making good progress was allowed to go out, lived unreasonably for six weeks, and came back with the lung in a gangrenous condition. One died of cerebral abscess. One outpatient said to have died of influenzal pneumonia, but probably a septic pneumonitis. Seven (15·5 per cent.) were referred for surgical treatment; 4 had lobotomy and of them 1 died, while 3 with secondary empyema recovered. The lobotomy death was that of a patient discharged a year previously apparently cured, who had a baby after discharge; she then had an attack of influenza and a light-up, but she did not return for six months. Death from hæmorrhage took place at the commencement of operation.
